Several small series have been published demonstrating the laparoscopic approach as safe, effective, and cost efficient when compared to the open technique. Postoperative complications between the open and laparoscopic groups are not significantly different. A major concern regarding the laparoscopic approach is the inability to reduce the intussusception using the standard retrograde fashion of the open technique. Some authors voice concern that a surgeon reducing an intussusception laparoscopically must apply pull and tension on an often friable segment of bowel, increasing the risk of bowel perforation. Additionally, because most cases of intussusception in older children are secondary to a pathologic lead point, the laparoscopic technique may not be appropriate in these patients. In order to minimize the rate of conversion to the open approach, the patient should be seen within 36 hours of the onset of symptoms and have no peritoneal signs. The role of laparoscopy in intussusception is evolving and will be better defined as technology progresses and experience with the minimally invasive approach to this disease grows.

Postoperative follow-up: Intravenous fluid resuscitation is continued and calculated, taking into consideration maintenance requirements and third-space losses. Upon resolution of ileus, diet is advanced at the discretion of the surgeon.

In older children and in cases of recurrent intussusception (after 3-4 episodes) successfully reduced with an enema, consider evaluating the patient for a lead point (e.g. upper GI series, Meckel scan).

Complications

Intussusception results in bowel obstruction; thus, complications such as dehydration and aspiration from emesis can occur. Ischemia and bowel necrosis can cause bowel perforation and sepsis. Necrosis of a significant length of intestine can lead to complications associated with short bowel syndrome. Whether treated by operative or radiographic reduction, late stricture (4-8 wk) may occur within the length of intestine involved.

Prognosis

The overall mortality rate of intussusception is less than 1 percent. Recurrence rates following nonoperative reduction and surgical reduction are approximately 5 percent and 1 to 4 percent, respectively. The following criteria are associated with a higher failure rate of nonoperative reduction:

- Raised neutrophil percentage
- Rectal bleeding
- Failed reduction with barium at another institution
- Age older than 2 years or younger than 3 months
- Duration of symptoms longer than 24 hours
- Small-bowel obstruction on radiograph
- Dehydration of greater than 5 percent
- Inexperienced radiologist.

Factors significantly predictive of bowel perforation are younger age and a longer duration of symptoms. The risk of postoperative adhesive small-bowel obstruction following nonoperative reduction is 0 percent; for operative reduction, it has been reported in as many as 5 percent of patients.

Transient intussusception diagnosed on Ultrasonography for pain abdomen, in the absence of clinical signs of intestinal obstruction, can safely be observed. One must look for lead points if intussusception occurs repeatedly, especially in bigger children. In doubtful cases contrast enema can be used.

CHOLECYSTITIS

Cholecystitis occurs when a calculus obstructs the cystic duct. The trapped bile causes inflammation of the gallbladder wall. As gallstones are often occult on CT, sonography is the preferred imaging method for the evaluation of cholecystitis, also allowing assessment of the compressibility of the gallbladder. The diagnosis of a hydropic gall bladder is solely made on the noncompressibility of the gall bladder. Do not rely on measurements. Some gallbladders happen to be small and others are large.

The imaging appearance of cholecystitis consists of an enlarged hydropic (meaning noncompressible) gallbladder with a thickened wall in the region of maximum tenderness (*Murphy sign*). The inflamed gallbladder usually contains stones or sludge, whereas the obstructing calculus itself may or may not be identified because it is located deep within the gallbladder neck or cystic duct. The gallbladder may be surrounded by inflamed fat, but on sonography this frequently is not seen, while CT sometimes does show fat-stranding. Potential pitfalls are pancreatitis, hepatitis or right-sided heart failure, which all may lead to thickening of the gallbladder wall without cholecystitis. Therefore, be certain that hydropic obstruction of the gallbladder is present before assigning the diagnosis of cholecystitis.

An acute abdomen with LUQ pain is rare. Its most common cause is gastric pathology in which radiological imaging plays a minor role. Inflamed fat is shown as fat-stranding at CT. Inflamed fat usefully points out where and what the problem is. As a rule, the organ or structure in the centre or nearest to the inflamed fat is the cause of the inflammation. Thickening of bowel wall indicates inflammation or tumor, and has an extensive differential diagnosis. Thickening

of small bowel loops usually indicates regional inflammation, as small bowel tumors (carcinoid, lymphoma, GIST) are relatively infrequent. In patients with local colonic wall thickening a carcinoma is a prime concern.

Small-bowel obstruction (SBO) accounts for approximately 4 percent of all patients presenting with an acute abdomen. The diagnosis of SBO is made when you see dilated small bowel and collapsed small bowel loops. If obstruction is present, try to identify its cause and location (adhesion, tumor, volvulus, intussusception, inguinal hernia). Adhesions account for 60 to 80 percent of all cases and are the likely cause when a smooth transition from dilated to collapsed small-bowel loops is noted. Bands or internal herniation associated with Meckle's diverticulum are an important cause of small bowel obstruction. Mal rotation with or without volvulus is an unusual cause of pain abdomen in children beyond infancy. If investigated during pain signs of obstruction may be present. However, during remission, clinical findings may not be present.

The 'Small Bowel Feces Sign' (SBFS)¹¹ is a very useful sign as it is seen at the zone of transition thus facilitating identification of the cause of the obstruction. The SBFS has been defined as gas and particulate material within a dilated small-bowel loop that simulates the appearance of feces.

ACUTE SCROTUM

The acute pain in scrotum should never be ignored, as the child is in real danger of losing his testis. The patient's history and physical examination are the key to the diagnosis and often guide decision making regarding whether or not surgical intervention is appropriate. Imaging studies should complement, but not replace, sound clinical judgment. When making a decision for conservative, nonsurgical care, the provider must balance the potential morbidity of surgical exploration against the potential cost of missing a surgical diagnosis. A small but real, negative exploration rate is acceptable to minimize the risk of missing a critical surgical diagnosis.

*Causes of Acute Scrotal Pain and Swelling.*¹²

Ischemic conditions

- *Torsion of the testis:* Intravaginal; extravaginal (prenatal or neonatal)
- Appendiceal torsion, testis or epididymis
- Testicular infarction due to other vascular insult (cord injury, thrombosis).

Trauma

- Testicular rupture
- Intratesticular hematoma, testicular contusion
- Hematocele.

Infectious conditions

- Acute epididymitis
- Acute epididymo-orchitis

- Acute orchitis
- Abscess (intratesticular, intravaginal, scrotal cutaneous cysts)
- Gangrenous infections (Fournier's gangrene).

Inflammatory conditions

- Henoch-Schönlein purpura (HSP) - vasculitis of scrotal wall
- Fat necrosis of scrotal wall.

Hernia

Incarcerated, strangulated inguinal hernia, with or without associated testicular ischemia.

Acute on chronic events

- Spermatocoele—rupture or hemorrhage
- Hydrocoele—rupture, hemorrhage or infection
- Testicular tumor with rupture, hemorrhage, infarction or infection
- Varicocele.

TESTICULAR TORSION (FIG. 9)

The testicle is typically covered by the tunica vaginalis, creating a potential space around the testis. Normally, the tunica vaginalis attaches to the posterior surface of the testicle and allows for very little mobility of the testicle within the scrotum. Some patients have an inappropriately high attachment of the tunica vaginalis, such that the testicle can rotate freely on the spermatic cord within the tunica vaginalis (intravaginal testicular torsion). This congenital anomaly, called the "bell clapper deformity," results in a transverse as opposed to longitudinal lie of the affected testes. This congenital abnormality is present in approximately 12 percent of human males (Fig. 10).

During testis torsion, the testicle twists spontaneously on the spermatic cord, causing venous occlusion and engorgement, with subsequent arterial ischemia and infarction. Experimental evidence indicates that 720° twist is required to compromise flow through the testicular

Fig. 9: Torsion left testis with retraction
(For color version see plate 15)

Fig. 10: Gangrene of testis (For color version see plate 15)

artery and result in ischemia. In neonates, the testicle frequently has not yet descended into the scrotum, after which it becomes attached within the tunica vaginalis. This increased mobility of the testicle predisposes it to torsion (extravaginal testicular torsion).

Testis torsion is the most common cause of testis loss. The incidence is approximately 1:4000. Torsion more often involves the left testicle. Among neonatal testicular torsion cases, 70 percent occur prenatally and 30 percent occur postnatally. The testis salvage rate approaches 100 percent in patients who undergo detorsion within 6 hours of the start of pain. However, there is only a 20 percent viability rate if detorsion occurs >12 hours; and virtually no viability if detorsion is delayed >24 hours.

CLINICAL PRESENTATION

Testicular torsion presents with the rapid onset of severe testicular pain and swelling. The onset of pain may be preceded by trauma, physical activity, or by no activity (e.g., during sleep). It most often occurs in children of adolescents. Torsion should be in the differential for any sudden acute scrotal pain or swelling.

The classic *physical examination* findings with testis torsion are an *exquisitely tender testicle* with a high, horizontal lie. Normally the testicle has a vertical lie within the tunica vaginalis of the scrotum – that is, the longitudinal axis of the testis is oriented vertically. With torsion and twisting of the spermatic cord, the testis may assume an altered lie based on the degree of twisting. After venous outflow is occluded, there is swelling and occlusion of arterial flow. Early on, one may be able to palpate the torted cord and

the testis below it; later in the course, however, progressive edema and inflammation ensues, such that after 12 to 24 hours, the entire hemiscrotum appears as a confluent mass without identifiable landmarks. At this stage, the physical examination may be indistinguishable from that seen with epididymo-orchitis. Importantly, with torsion, signs of infection are usually absent: patients are usually afebrile, free of irritative voiding symptoms such as dysuria, and harbor a normal urinalysis and normal white blood cell count. (In later torsion, however, an elevated WBC may be seen in response to the inflammation).

Diagnosis is mainly clinical – acute onset of symptoms, excruciating pain and classical examination findings as described above. However, confirmation may be made either a nuclear scan or a color Doppler study to look for the vascular flow of testicle. Inflammatory pathology will reveal normal or increased vascularity while torsion will show reduced or absent blood supply to the affected organ.

Treatment

Surgical intervention is urgent, without wasting time for investigations. Investigations should be carried out only during the time operation theater is being prepared. An attempt should always be made to derotate and give the organ a chance to regain its vascularity. However, if, after a suitable time lag, there is no change in color of the testicle, an orchidectomy should be done (Fig. 9). Doubtful testicle should be left alone and reviewed later if required.

STRANGULATED INGUINAL HERNIA

An inguinal hernia is a common surgical entity and is an emergency only if *irreducible*. The risk of irreducibility is always associated with an inguinal hernia, more so in neonates and infants. An irreducible hernia progresses to *intestinal obstruction* when the lumen of entrapped bowel gets occluded due to ensuing edema or the bulk of the contents. However, the most sinister is the *strangulation*, when the entrapped organs lose their blood supply and are in imminent danger of gangrene. By the time the stage of strangulation is reached, the child may already be dehydrated due to intestinal obstruction and vomiting. He may be toxic due to devitalized bowel, and have tachycardia and fever. The affected hemiscrotum may be exquisitely tender and angry looking. The surgical exploration is urgent and a laparotomy may be more appropriate. The gangrenous bowel/ the bowel which fails to regain its blood supply needs to be resected.

Reducible inguinal hernia → Irreducible inguinal hernia → Obstructed inguinal hernia → Strangulated hernia
Surgical options – Reducible inguinal hernia - Elective herniotomy

Irreducible inguinal hernia - Reduce and elective herniotomy

Obstructed inguinal hernia - Emergency surgery
 Strangulated hernia - Urgent laparotomy.

Common Surgical Problems for the Pediatrician in Office Practice

Sushmita N Bhatnagar

INTRODUCTION

Keep me away from the wisdom which does not cry, the philosophy which does not laugh and the greatness which does not bow before children.

—Khalil Gibran

To deal with children is a challenging task and to deal with those with illnesses is in itself a herculean effort. But with compassion, love and understanding of the several conditions which affect them, we could manage them appropriately and give the young lives and young minds a safe and comfortable future, which is what this famous quote says.

A child who has to undergo surgery is dealing with not only physical illness, but also the psychological impact of undergoing surgery and its effects apart from the physiological stress of a surgical procedure. Hence, dealing with children with surgical conditions has to take into account all of these factors so as to decrease his/her anxiety, minimize the psychological trauma and promote healing of the surgical wound. Studies have indicated that postoperative recovery has been delayed if the preoperative preparation is not adequate.¹ Whether the child is first seen by a general practitioner, a pediatrician, a physician, or even an adult surgeon before being referred to Pediatric Surgeon, it is important to allay the anxiety of the parents as well as the child as anxiety in children undergoing surgery is expressed in various forms.² Also important is the timing of surgical intervention, which affects the outcome of the condition.

Several other essential considerations in children include a proper understanding of pathophysiology of the underlying condition, an accurate calculation of the losses of fluids, of blood and adequate replacement of these in the surgical conditions. Imperative to a good outcome is adequate preoperative preparation as surgery is a major

event in the life of the child. This includes preparation of the child and parents for surgery; in terms of acceptance of the surgical procedure, the time required for recovery, adequate nutrition before and after surgery, and prevention of infections during this period.

The common conditions which the pediatricians come across in their office practice are classified as follows:

- Genitourinary conditions
 - Hernia (inguinal, umbilical)
 - Hydrocele
 - Undescended testis
 - Hypospadias
 - Labial synechiae
 - Phimosis
- Injuries and burns
- Gastrointestinal conditions
 - Abdominal pain
 - Constipation
 - Vomiting
- Surgical infections
 - Abscesses (with or without lymphadenopathy)
 - Necrotizing fasciitis

GENITOURINARY CONDITIONS

Inguinal Hernia

The word hernia comes from Hippocrates who used the Greek *hernias* for bud or bulge to describe abdominal protrusions. Androise Pare about 400 years ago described treatment of incarcerated hernia with trusses. In spite of the advances in technology and science, inguinal hernia still remains a surgical disease and all hernias need to be surgically corrected (Fig. 1).

Hernia present as inguinal or sometimes inguinoscrotal swelling which increases (while coughing, crying, running) and decreases/disappears (while sleeping) in size. Herniae

Fig. 1: Large left sided inguinal hernia
(For color version see plate 16)

Fig. 2: Bilateral small hydroceles
(For color version see plate 16)

need surgery at the earliest, the younger the child, the earlier the need to operate due to high chances of incarceration, obstruction and testicular infarction and necrosis.

Another entity which needs special mention is fluid hernia, wherein the sac contains only fluid and not bowel loops. This is often termed as communicating hydrocele. The treatment for this condition remains surgical.

Hernia in a girl child is a similar entity and requires similar treatment, except with a slight difference in that a preoperative assessment to rule out disorder of sexual development is necessary in all. It was thought of in the past that girls have a higher incidence of femoral herniae, but even in females the incidence of inguinal herniae are more common than the femoral counterpart.³

Umbilical Hernia

The incidence of umbilical hernia is highest in the newborn period and gradually decreases with increasing age. Umbilical hernia is either congenital or acquired. Majority of these are congenital, the acquired ones are associated with gross ascites or any condition with increased intra-abdominal pressure such as children with hydrocephalus in whom a Ventriculo-peritoneal shunt has been performed. This indicates the defect in the umbilical ring. The differential diagnosis includes paraumbilical hernia, minor omphalocele.

Most of the umbilical herniae are isolated conditions, but infrequently large umbilical herniae are associated with mucopolysaccharide storage disease (such as Hunter-Hurler syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome), Beckwith-Wiedemann syndrome, Down's syndrome, congenital hypothyroidism, fetal hydantoin syndrome, Freeman-Sheldon syndrome.⁴ The size of the umbilical defect varies from 1 cm to 5 cm usually but more than 5 cm occasionally. Clinically these herniae increase on crying, coughing, sitting, walking, straining and reduce on sleeping often completely. Most

of the umbilical hernia present as painless bulge, but some present as pain in abdomen which occurs due to drag on the mesentery along with bowel loops into the hernial sac.

When the size is small <1 to 2 cm, the chances of strangulation of bowel loops increases and so is the incidence of spontaneous closure. Closure or repair of the hernia is unnecessary in children less than 3 years of age as spontaneous closure occurs in up to 85 percent of children with small defects.⁵ Larger defects even though the risk of complications is very low, often require surgical intervention earlier as spontaneous closure is very unlikely.

Hydrocele

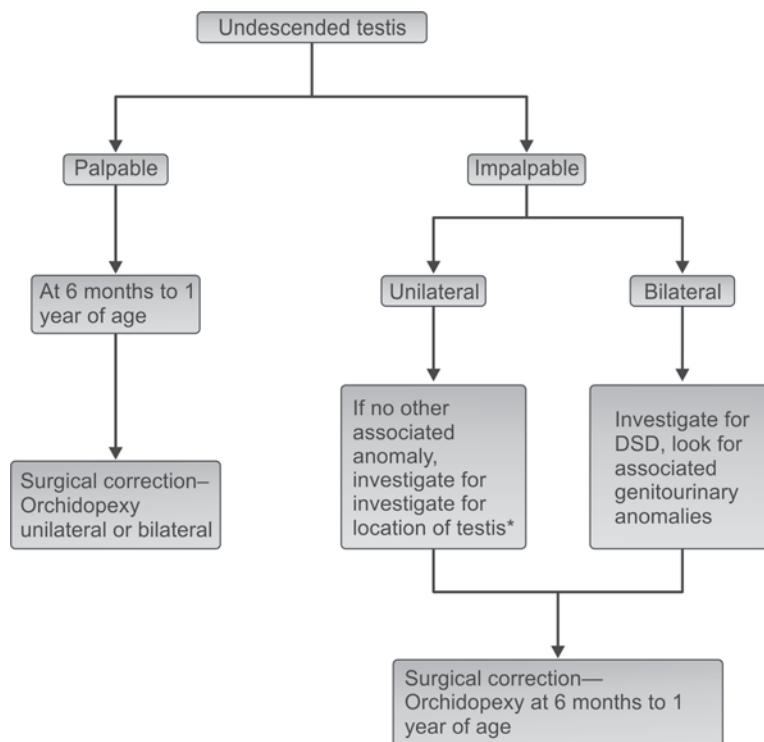

Hydroceles present as scrotal swelling or sometimes inguinoscrotal swelling which does not show much change in size. These are collections of fluids around the testicles which gradually get reabsorbed (Fig. 2). In children less than 2 years of age, no surgical intervention is required as the hydrocele may completely disappear, unless the hydrocele is very large in size, is growing rapidly or is causing pain.

Distinguishing hernia from hydrocele is important as the treatment plan for both the conditions varies. Reducing the swelling and getting above the swelling are two important clinical landmarks to differentiate both these conditions. In hernia, surgery is to be done at the earliest, whereas in hydrocele surgical intervention is deferred till about 2 years of age.

Undescended Testis

Undescended testis (UDT) is the most common birth defect concerning the male genitalia. A child could have unilateral or bilateral undescended testis (cryptorchidism) (Fig. 3). Also important to note is whether the undescended testis is palpable or impalpable. The management of child with UDT is dependant on the above parameters. A management algorithm is hereby described in Flow Chart 1.

Flow chart 1: Undescended testis

*Laparoscopy has been a decisive modality of investigation for nonpalpable undescended testis.^{6,7} It also helps in differentiating true undescended testis from atrophic testis and vanishing testis

Fig. 3: Bilateral undescended testis
(For color version see plate 16)

Fig. 4: Penoscrotal hypospadias with chordee
(For color version see plate 16)

Hypospadias

Hypospadias is a purely surgical condition in which the opening of the urethral meatus which is ectopically located on the ventrum from the scrotal to the glans (Figs 4 and 5). There are about 300 different types of operative procedures described in literature, and it is up to the surgeon to select the type of repair that he/she is

most comfortable with. In recent times with improved instrumentation, improved pre- and postoperative care and antibiotics and with newer techniques, the focus is on single stage repair for most hypospadias except the severe penoscrotal and scrotal types with severe chordee. Three crucial considerations in any child with hypospadias are:

Fig. 5: Distal penile hypospadias with left congenital hydrocele
(For color version see plate 16)

Fig. 6: Phimosis (pathological)
(For color version see plate 16)

- Any severe hypospadias needs to be investigated for disorder of sexual differentiation (DSD).
- Circumcision should never be done in child with any type of hypospadias as the foreskin is required for reconstruction.
- The timing of repair on an average is between 1 to 2 years of age and all stages of surgical correction must complete before the child is of school going age.

Labial Synechiae

Adhesions between the labia minora result in labial synechiae which are a common general pediatric presentation in office practice. Since there are many misconceptions, girls with this condition often undergo unnecessary investigations for ambiguous genitalia and surgical procedures for correction. Depending on the severity of the adhesions, the child could be asymptomatic and brought for abnormal appearance of genitalia or present with severe urinary complaints like burning micturition, dribbling, thin stream and urinary tract infection.

The treatment is division of the adhesions in the outpatient department with a probe or an artery forceps after application of local anesthetic cream such as lidocaine and application of estrogen/steroid creams three times in a day for about 4 to 6 weeks.^{8,9}

Phimosis

Phimosis is the most commonly encountered condition in office practice (Fig. 6). Almost every male child presents to the OPD either with symptoms (less commonly), but mainly without symptoms but with inability to retract the prepuce. This subject has been widely discussed in

multiple forums, but one needs to remember the following significant features which are essential for unnecessary surgical interventions. These are as follows:

- All boys have phimosis at birth, known as physiological phimosis. This condition does not need any intervention. As the child grows, the prepuce gradually opens up and starts retracting, the process completing by about 6 to 7 years of age. Differentiation between physiological and pathological phimosis is crucial for further management.
- Some boys present with symptoms such as ballooning of prepuce, thin stream, recurrent balanoposthitis and urinary tract infection. All except ballooning of prepuce need some form of intervention. Ballooning of prepuce is not an indication for circumcision.
- Circumcision is not the only treatment option for pathological phimosis. Lesser surgical options include preputial retraction under local or general anesthesia followed by steroid cream applications over a period of 4 to 6 weeks to prevent rephimosis and prepuceoplasty in which the prepuce is not excised thus maintaining the normal anatomy and function of the prepuce.¹⁰ Several different techniques for prepuceoplasty are described in literature, but the technique designed by the author is a ventral vertical incision and transverse suturing thus dividing the preputial ring and enlarging the prepuceal orifice for easy retraction of prepuce.

INJURIES AND BURNS

Children of all ages are injured very frequently. The degree of injury ranges from minor to major and the differentiation or identification of each category and appropriate triage of each child is of primary significance.

The main reasons for injuries in children are:

- **Falls:** All falls do not lead to internal organ injury, but all children who have had a fall must be assessed for injury to the three main parts; the head, the chest and the abdomen. Injuries to these parts even though may seem minor must be monitored closely, either in a hospital setting or at home by an experienced and qualified person.
- **Cuts and bruises:** Most of these are trivial injuries. Those on the face, tongue and genital area need a detailed assessment and many a times surgical intervention to prevent excessive bleeding or disfigurement.
- **Burns:** The most common burns in children are the scald injuries which are superficial. These burns can be managed at primary care level and even at home. Prevention of infection should be a primary focus. Whatever the cause of the burns, if the surface of burns is larger or if the severity and the degree of burn is greater, a tertiary care center and an experienced medical professional is necessary.

Tips for burns in children include:

- Remove the cause for causing burns immediately.
- Reduce the temperature of the burnt area, but ice application is not to be done as it increases the skin damage.
- Assess the surface of the burnt area. If more than 10 percent body surface is burnt, immediate hospitalization is essential as there is rapid fluid shift leading to severe dehydration in children.
- Burns on the head, face, neck, hands, joints and genitals need immediate attention. In facial burns due to fire, edema of the respiratory tract occurs very rapidly and causes complete obstruction which could lead to rapid death.
- Chemical and electrical burns are misleading as to the area involved and severity, hence must not be treated at home or primary care unit.

GASTROINTESTINAL CONDITIONS

Abdominal Pain

Abdominal pain can be really worrying at times and children do tend to suffer from abdominal pain at some point or the other. It is important to differentiate between an acute abdominal pain and a chronic one. The acute abdomen can be due inflammatory or obstructive causes, both of which need to be attended to immediately. The child could be having appendicitis, typhilitis, typhoid, intussusception, or calculus in the kidney or ureter causing acute

pain. The treatment depends on the cause of pain, but generally almost all of these children need intravenous antibiotics and sometimes surgical intervention on an emergency basis.

The chronic pains could be either recurrent abdominal pain (RAP) or non-specific abdominal pain (NSAP). The cause for both could be either organic or psychogenic. Evaluating the cause and a detailed study is mandatory before surgical intervention is contemplated.

Without serial observations, abdominal pain in the child should not be neglected. Surgical opinion should be sought in the following circumstances:

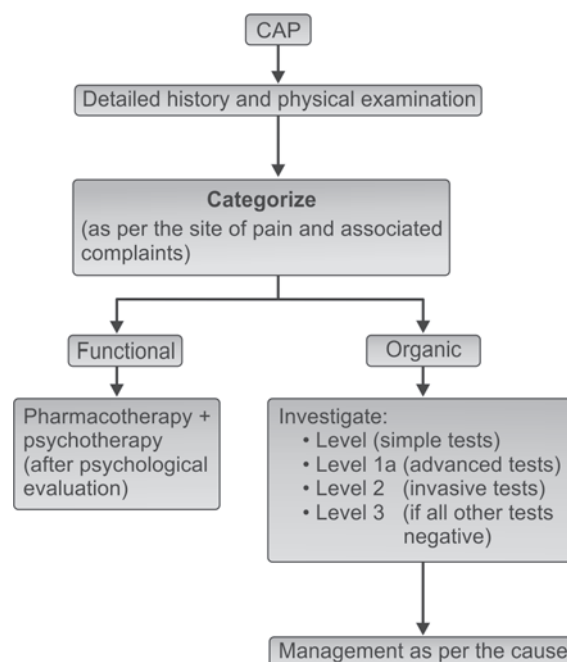

- Continuous/Colicky severe abdominal pain for more than 6 hours
- Pain with nausea and vomiting
- Fever with abdominal pain
- Tenderness of the abdomen
- Bilious vomiting associated with pain
- Pain associated with urinary complaints.

Chronic abdominal pain (CAP) is a challenging problem both for the pediatrician and the pediatric surgeon. While it is difficult to pinpoint the exact cause of CAP, it is important to workup these children in a systematic manner.¹¹ A simple algorithm is described in Flow chart 2.

Constipation

In the present era wherein children regularly consume junk food and low fiber diet, the presenting complaint of constipation with or without pain in abdomen occurs in about 30 to 40 percent of children coming to the outpatients department.

Flow chart 2: Chronic abdominal pain

Though there are many existing definitions of constipation, the Paris consensus on childhood constipation terminology (PACCT) defines constipation as “a period of 8 weeks with at least 2 of the following symptoms: defecation frequency less than 3 times per week, fecal incontinence frequency greater than once per week, passage of large stools that clog the toilet, palpable abdominal or rectal fecal mass, stool withholding behavior, or painful defecation.”¹²

A thorough dietary history is absolutely mandatory before labeling a child as habitual constipation or Hirschsprung's disease. Clinically the pointers for Hirschsprung's disease are:

- History of delayed passage of meconium
- No passage of flatus
- No soiling (which is common with habitual constipation)
- Abdominal distension
- *On per rectal examination:* Stools not felt at the anal verge and expulsive passage of feces on withdrawing finger
- Plain X-ray abdomen showing large gas filled dilated loops with or without air-fluid levels (large dilated loops absent in children with habitual constipation).

Treatment depends on the causative factor. Whilst habitual constipation has to be corrected with diet, laxatives, suppositories and occasionally enemas, Hirschsprung's disease needs surgical intervention for all types.

Vomiting

The causes of vomiting in children vary as per the age of the child. Also, it is more common in infants than in older children, often with conditions affecting systems other than gastrointestinal tract. Important considerations in a child with vomiting are:

- Associated weight loss (Gastroesophageal reflux)
- Lump in abdomen (Pyloric stenosis/solid abdominal tumor)
- Bilious vomiting (Intestinal obstruction/Peritonitis/Septic ileus)
- Coffee ground vomit or fresh blood in vomit (Portal hypertension/Mallory-Weiss disease)
- Associated high grade fever (any infective condition, abdominal or extra-abdominal).

A child with vomiting needs urgent attention if the vomiting is recurrent and if there is accompanied refusal of feeds. Investigations for diagnosis can wait till dehydration is corrected. Hemoglobin levels and serum electrolytes are mandatory in such children. Blood grouping and cross matching should be done in all such children as surgical intervention may be needed in a majority of these children.

SURGICAL INFECTIONS

Abscess

Soft tissue infections in children lead to formation of abscesses. For superficial small abscesses on the skin,

systemic antibiotics are not necessary, but deep lesions in children require hospitalization, intravenous antibiotics and surgical drainage irrespective of the site of occurrence. Abscess in the pleural cavity (empyema) is the most common site of internal abscess. Abscesses in the brain, kidney, liver, pericardium could be fatal, hence need rapid diagnosis and multimodality treatment.

Necrotizing Fasciitis

This is a severe life-threatening condition resulting in a rapid necrosis of the soft tissues including fascia and subcutaneous tissues. It could be primary infection from the skin or could be secondary as part of systemic septicemia. Either way, surgical debridement and appropriate broad spectrum antibiotics must be instituted early to prevent mortality.¹³

Pediatric Poisonings: Emergency Room Assessment and Management

Suresh Gupta

BACKGROUND

Optimal management of the poisoned patient requires recognition and integration of available key resources. The management and investigation of the poisoned patient, like other clinical situations, is enhanced by the ability to access expert resources like poison control center or clinical toxicologist. The goals of this chapter are:

- To provide an approach for the assessment and diagnosis of poisonings
- To provide a generic approach to managing common poisonings and their complications
- To provide a framework for consideration of a poisoning etiology in the clinician's differential diagnosis.

This chapter is not all inclusive or comprehensive but is intended to provide a framework for the clinical approach and management of the poisoned patient. The general approach to the poisoned patient can be summarized as:

- Stabilization
- History
- Examination
- Diagnosis
- Decontamination
- Enhanced elimination
- Poison-specific treatment
- Disposition (Flow chart 1).

Clinicians should have a high index of suspicion and be quick to consider an alternate toxin or medical condition in cases where the history is inconsistent with the patient's clinical presentation. In difficult cases, if it is felt appropriate, the physician should consult with the poison control center or a clinical toxicologist.

STABILIZATION

Stabilization is the first priority in managing toxic ingestion. The patient should be rapidly assessed to determine

adequacy of airway and ventilation, mental status, and cardiovascular function. At this point, the clinician should also search for and correct hypoxia and hypoglycemia. Initial management priorities are maintenance and protection of the airway, support of ventilation, and support of circulation. Unstable patients should be placed on a cardiac monitor with measurement of vital signs every 5 to 15 minutes until the patient is stabilized to the point where monitoring is no longer necessary. The potential for rapid changes in the patient's condition should be considered in making decisions about airway and ventilatory support.

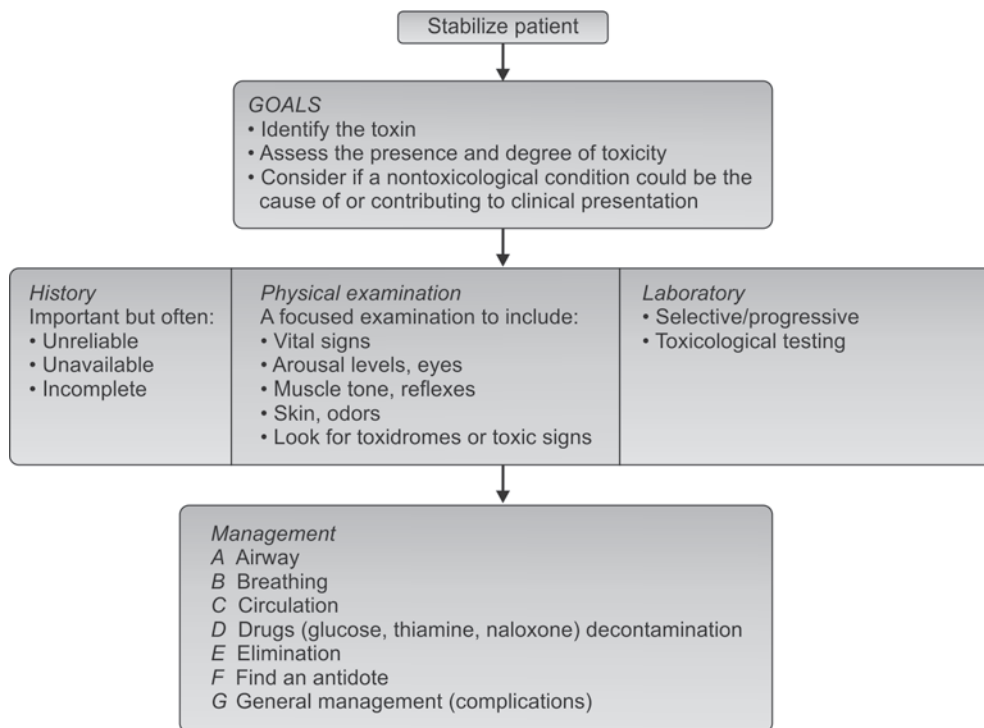

Managing Common Complications

Common complications of poisoning include depressed mental status, seizures, agitation, hypotension, bradycardia, and vomiting. Most of these can be treated empirically without knowledge of the toxin involved and without specific antidotes (Table 1). Management of these complications occurs concurrently with history, physical examination and specific laboratory tests.

Coma and Altered Mental Status

- Concurrently with the "ABC's", (airway, breathing, and circulation) the clinician must search for and treat hypoglycemia, hypoxia, head injury, CNS infection, and sepsis.
- Oxygen saturation should be measured in all comatose patients or patients with altered mental status. All of these patients should be given supplemental oxygen.
- Bedside this, glucose testing should be performed in all patients with altered mental status. Administer intravenous dextrose (adults: D50W; children D25W in dose of 2-4 cc/ kg). Glucose should be given immediately to all persons with suspected hypoglycemia even if the glucometer reading is normal (since false

Flow chart 1: Assessment and management of a poisoned patient

negatives can occur). It is dangerous to wait for the formal laboratory measurement of glucose before giving D50W.

- Naloxone may be given to all obtunded patients or reserved for those with hypoventilation, small pupils, or history of opioid use. In apneic patients, the initial dose of naloxone is 2 mg in adults and 0.1 mg/kg in children. Most patients will respond to small doses of naloxone but up to 10 mg may rarely be required.
- Flumazenil, a benzodiazepine antagonist, should not be routinely administered in the patient presenting with coma or altered mental status. Reversal of benzodiazepine effect in mixed drug ingestion involving cyclic antidepressants and chloral hydrate may result in seizures or arrhythmia with fatal outcomes.

Seizures

- Toxic seizures are often transient, in which case no specific treatment is required.
- When treatment is required, benzodiazepines (e.g. diazepam or lorazepam) are usually effective.
- If benzodiazepines fail, barbiturates (e.g. phenobarbital) almost always suffice.
- Phenytoin probably has no role in toxin-induced seizures and is theoretically harmful in tricyclic poisoning.

- Phenytoin also has no role and is harmful in theophylline overdoses.
- Isoniazid may cause severe seizures that respond poorly to the usual treatment. Pyridoxine (Vitamin B₆) is required in these unusual poisonings.

Agitation

- Severe agitation presents a risk to both the patient and health care providers and should be considered as a medical emergency.
- Police or paramedics who bring a severely agitated patient to the hospital should be asked to remain until the patient has been safely restrained and adequately sedated.
- Immediately life-threatening causes such as hypoxia, hypoglycemia, head injury, and CNS infection should be considered and treated as indicated.
- Management consists of pharmacological sedation, judicious use of physical restraint and a diligent search for a life-threatening cause of agitation.
- Venous access can usually be achieved with sufficient manpower and it is preferable to use intravenous rather than intramuscular sedation.
- Benzodiazepines such as diazepam or lorazepam (titrate to effect in aliquots of 5 to 10 mg every 5 minutes in adults or 0.1 mg/kg in children) are the drugs

Table 1: Treatment options for managing common complications**Agitation**

<i>Situation</i>	<i>Pharmacological management</i>
<ul style="list-style-type: none"> • Most agitated patients • Belligerent drunk 	<ul style="list-style-type: none"> • Diazepam or lorazepam • Haloperidol

Adjunct management

- Ask police, paramedics, or hospital security to assist with restraining patient if required
- Look for and treat other causes of agitation:
 - Hypoglycemia
 - Hypoxia
 - Brain injury
 - Infectious causes
 - Measure temperature and cool if indicated

Altered mental status*

<i>Clinical condition</i>	<i>Treatment</i>
<ul style="list-style-type: none"> • Hypoxia • Hypoglycemia • Opiate overdose 	<ul style="list-style-type: none"> • Oxygen • Glucose, thiamine (in adults) • Consider naloxone hydrochloride

* Treatment of the most common causes of altered mental status that can be recognized and treated in the first five minutes of care

Drug-induced bradycardia

<i>Situation</i>	<i>Treatment</i>
<ul style="list-style-type: none"> • Bradycardia in general 	<ul style="list-style-type: none"> • Treat underlying cause like hypoxia, electrolyte disturbances, etc. • Atropine • External or internal pacemaker
<ul style="list-style-type: none"> • Digoxin poisoning • Opiate overdose 	<ul style="list-style-type: none"> • Digibind® • Naloxone hydrochloride

Hypotension

<i>Toxin</i>	<i>1st line therapy</i>	<i>2nd line therapy</i>	<i>3rd line therapy</i>
General drug-induced hypotension	Normal saline fluid bolus	Dopamine infusion*	
Hypotension secondary to β -blockers	Normal saline fluid bolus	Glucagon bolus followed by infusion if necessary	Epinephrine infusion*
Hypotension secondary to calcium channel blockers	Normal saline fluid bolus	Calcium infusion glucagon bolus followed by infusion if necessary	Epinephrine or Dopamine infusion*
Hypotension secondary to cyclic antidepressants or membrane depressant drugs	Normal saline fluid bolus	Sodium bicarbonate bolus	Norepinephrine infusion*

*Titrate to maintain systolic BP above 3rd centile (in children above 10 year >90 mm Hg)

Seizures

<i>Toxin</i>	<i>Initial therapy</i>	<i>Refractory seizures</i>
General drug-induced seizure	Benzodiazepine - diazepam or lorazepam	Phenobarbital
Isoniazid (INH)	Benzodiazepine Diazepam or lorazepam	Pyridoxine Thiopental (must intubate patient)

of choice for rapid sedation in most cases of toxin-induced agitation. However, it carries the risk of respiratory depression in patients poisoned with alcohol or another sedative.

- Agitated patients often develop life-threatening hyperthermia, so an accurate measurement of temperature is imperative in all of these patients. Patients who feel hot to touch should be cooled empirically if there is any delay in obtaining an accurate temperature.

Hypotension

- Drug-induced hypotension is most often caused by vasodilation or volume loss and usually responds to fluids or catecholamine pressors.
- Bicarbonate may be required for hypotension caused by tricyclic antidepressants or other drugs that inhibit sodium channels.
- Hypotension caused by cardiotoxic drugs such as β -blockers, calcium channel blockers, or sodium channel blockers may require glucagon, calcium, or catecholamine pressors. A clinical toxicologist should be involved early in the management of such cases.

Drug-Induced Bradycardia

- Agents causing bradycardia are listed in Table 2.
- Opiates cause moderate bradycardia that responds to naloxone.
- Standard doses of atropine (0.5 to 3 mg in adults and 0.01 mg/kg in children) may be effective in mild cases of drug-induced bradycardia.

- Large doses of atropine may be required to treat bradycardia and other toxicity caused by cholinergic agents such as organophosphate insecticides.
- Pacemakers should be considered when bradycardia fails to respond to atropine. Pacemakers should be avoided in digoxin overdose because of the risk of inducing ventricular dysrhythmias.
- Digoxin induced bradycardia may require Digibind® (digitalis antibodies).
- Bradycardia caused by calcium channel blockers or β -blockers is often difficult to treat and may require glucagon, catecholamine infusions, or more specialized therapy.
- Clinical toxicologist should be consulted for these patients with significant drug-induced bradycardia, especially if it does not respond to atropine.

Intractable Vomiting

- Toxin-induced intractable vomiting usually responds to metoclopramide. The initial dose is 10 mg in adults or 0.1-0.2 mg/kg in children intravenously and a total dose of up to 1 mg/kg may be required.
- When metoclopramide fails, a more potent agent such as ondansetron (8 mg IV over 15 minutes) may be required.
- Vomiting associated with activated charcoal administration may be treated by having the patient take charcoal through a straw or through a nasogastric tube. Administering activated charcoal through the nasogastric tube by slow drip rather than by push may be successful in these circumstances.

Table 2: Toxic conditions and causative agents (limited list)

Agitated delirium	<ul style="list-style-type: none"> • Alcohol toxicity/withdrawal • Anticholinergics • Hallucinogens 	<ul style="list-style-type: none"> • Phencyclidine • Sympathomimetics (e.g. cocaine)
Anion-gap acidosis (MUD-PILE CATS)	<ul style="list-style-type: none"> • Methanol • Uremia • Ketoacidosis—diabetic, starvation, alcoholic <p><i>Note:</i> Common are ketoacidosis, lactic acidosis, salicylates. If these excluded toxic then alcohol poisoning like ethanol/ethylene glycol should be considered</p>	<ul style="list-style-type: none"> • Paraldehyde, phenformin, metformin • Iron, isoniazid • Lactic acidosis • Ethylene glycol • Cyanide • Acetyl salicylic acid • Toluene • Solvents
Bradycardia	<ul style="list-style-type: none"> • β-blockers • Ca-channel blockers • Digoxin <p><i>Note:</i> The “big three” causes are β-blockers, calcium channel blockers, and digoxin</p>	<ul style="list-style-type: none"> • Alpha agonists (e.g. phenylpropanolamine) • Beta 2-antagonists • Clonidine • Cholinergic agents • Opiates • Cyclic antidepressants

Contd...

Coma/obtundation	<ul style="list-style-type: none"> • Alcohols • Anticholinergics • Anticonvulsants: Barbiturates, phenytoin, carbamazepine, valproate, etc.) • Cholinergics <p><i>Note:</i> Any toxin that causes seizures or hypotension will also cause obtundation or coma</p>	<ul style="list-style-type: none"> • Neuroleptics (phenothiazines, butyrophenones, etc.) • Sedative hypnotics (e.g. benzodiazepines, chloral hydrate, meprobamate, etc.) • Opiates • Oral hypoglycemics • Tricyclic antidepressants
Elevated osmolal gap	<ul style="list-style-type: none"> • Ethylene glycol <p><i>Note:</i> Most important causes are methanol and ethylene glycol. Also consider shock, trauma, organ failure, or nonalcoholic ketoacidosis as causes of an elevated osmolal gap</p>	<ul style="list-style-type: none"> • Propylene glycol • Isopropyl alcohol • Mannitol • Methanol • Ethanol
Hypotension	<ul style="list-style-type: none"> • Angiotensin-converting enzyme inhibitors • β-blockers • Ca-channel blockers • Iron 	<ul style="list-style-type: none"> • Phenothiazines • Sedative hypnotics • Theophylline • Tricyclic antidepressants • Vasodilators
Radio-opaque compounds	<ul style="list-style-type: none"> • Chloral hydrate • Heavy metals • Iron • Phenothiazines 	<ul style="list-style-type: none"> • Sustained-release (enteric coated) compounds • Toxins in containers (e.g. body packers)
Seizures	<ul style="list-style-type: none"> • Alcohol withdrawal • Sedative hypnotic withdrawal • Amphetamines • Anticholinergics • Caffeine <p><i>Note:</i> Any toxin that causes hypotension or hypoglycemia can also cause seizures. Intractable seizures not responsive to usual management may be caused by isoniazid</p>	<ul style="list-style-type: none"> • Camphor • Carbamazepine • Cocaine • Isoniazid • Oral hypoglycemics • Propranolol • Propoxyphene • Sodium channel blockers • Theophylline • Tricyclic antidepressants
Sodium channel blockade	<ul style="list-style-type: none"> • Antihistamines (large overdoses) <p><i>Note:</i> Drugs with membrane stabilizing effect, or the ability to inhibit fast sodium channels, cause a significant number of fatalities. Toxicity is characterized by coma, seizures, hypotension, arrhythmias and a widened QRS on ECG</p>	<ul style="list-style-type: none"> • Carbamazepine • Class Ia and Ic antiarrhythmics • Cocaine • Mesoridazine • Propranolol • Propoxyphene • Thioridazine • Tricyclic antidepressants
Tachycardia	<ul style="list-style-type: none"> • Amphetamines • Angiotensin converting enzyme (ACE) inhibitors • Anticholinergics • Cocaine • Iron 	<ul style="list-style-type: none"> • Phenothiazines • Sedative hypnotics • Theophylline • Vasodilators (e.g. nitroglycerin) • Tricyclic antidepressants

- When vomiting complicates whole bowel irrigation, the procedure should be stopped until vomiting is controlled, then restarted at a lower rate.
- Numerous toxins may cause vomiting in overdose. Common causes of severe vomiting include digoxin, lithium, iron, theophylline, heavy metals, acetaminophen and ASA.

HISTORY

- History and physical examination are performed concurrently with stabilization.
- The history should include the five “W”s:
 - Who:* The patient’s age, weight, relationship to others present, and gender
 - What:* The name and dosage of medication(s) or substance(s) of abuse or other coingestants and amount ingested
 - When:* The time and date of ingestion
 - Where:* The route of poisoning
 - Why:* Whether intentional or accidental, and associated details.
- Other important historical points include a review of systems, specifically the presence of seizures, agitation, coma, vomiting, headache, and shortness of breath.
- Clinicians should be aware that in some cases the history is unreliable. Patients may not know what they ingested, the patient’s altered mental status or psychosis may impede communication, or the patient may intentionally mislead the clinician.
- Clinicians should have a high index of suspicion and be quick to consider an alternate toxin or medical condition in cases where the history is inconsistent with the patient’s clinical presentation. In such difficult cases, consultation with clinical toxicologist or poison control center may prove helpful.

PHYSICAL EXAMINATION

- A complete physical examination should be performed to detect complications and to help with the diagnosis.
- Specific attention should be paid to vital signs, mental status (depressed or agitated), respiration (depressed, evidence of pulmonary edema or aspiration), pupils (size, reactivity, presence of nystagmus), skin (diaphoresis or abnormally dry, blisters) and bowel sounds (increased or decreased).
- Based on findings from physical examination, the clinician should specifically consider the presence of a toxidrome. Common toxidromes are given in Table 3.

DIAGNOSIS

- Identification of the toxin involved is based on history, physical examination and clinical course as well as selected diagnostic tests (see below).

- Review of Table 2 (toxic conditions and causative agents) and Table 3 (common toxidromes and causes) may help suggest a causative agent. Specific drug levels (as discussed below) may be helpful in confirming the diagnosis and in making management decisions.
- Additional tests for an intentional overdose include the following:
 - An electrocardiogram as a screen for poisoning with tricyclic antidepressants or other cardiotoxic agents (tricyclics cause widened QRS intervals and tachycardia)
 - Chest radiographs are useful to detect pulmonary damage in patients with suspected aspiration, non-cardiogenic pulmonary edema, or other lung injury
 - Abdominal radiographs are useful screening tools in patients who may have ingested radiopaque material such as lithium, iron, lead, and other heavy metals. Drug packet and enteric-coated compounds may also be detectable on plain films.

DECONTAMINATION

After the patient is stabilized, consideration should be given to removing the toxin. The choice of decontamination should be made based on the clinical status and the suspected toxin.

Inhalation Exposure

Patients with an inhalation exposure should be removed from the source, with care taken to avoid exposure of the rescuers.

Cutaneous Exposure

When toxic compounds have been splashed into the eyes or onto the skin, copious irrigation with water is usually enough to remove the poison.*

Note: An important exception is hydrofluoric acid, which can cause chemical burns. Skin exposed to hydrofluoric acid should be covered with calcium containing gels. If this fails to relieve pain, calcium salts must be infiltrated locally or delivered through an arterial line.

Ingested Toxins

It is reasonable to withhold decontamination in patients who have taken a nontoxic or minimally toxic ingestion.

- Single dose *activated charcoal* is the preferred method of gastrointestinal (GI) decontamination for the vast majority of toxic ingestion
- Induced emesis with Ipecac has little role in adult or pediatric poisonings in either the hospital or prehospital phase
- Current thinking places a decreasing emphasis on the role of *gastric lavage*. Lavage should not be used routinely as its use may be associated with significant

Table 3: Common toxidromes and causes

<i>Toxidromes and causes</i>	<i>Characteristics</i>
Alcohol withdrawal	<ul style="list-style-type: none"> • Delirium • Tachycardia • Hypertension • Hyperthermia • Tremors beginning in first 5 to 10 hours • Seizures are generalized and are typically isolated or occur in a brief flurry beginning at 6 to 48 hours after reduced intake. Focal or protracted seizures are atypical and warrant investigation. • Delerium tremens in some patients after several days
Anticholinergic toxidrome Antihistamines, antipruritics anti-cholinergic (datura), cyclic antidepressants, antiparkinsonian agents, antiemetics, antispasmodics	<ul style="list-style-type: none"> • Altered mental status (hallucinations, agitation, coma) • Tachycardia • Large pupils • Dry skin • Decreased bowel sounds • Urinary retention
Cholinergic toxidrome Organophosphate, Carbamate insecticides	<ul style="list-style-type: none"> • Lacrimation, salivation • Bradycardia • Respiratory secretions • Hypoxia • Diaphoresis • Increased bowel sounds • Vomiting • Diarrhea and urinary incontinence • Fasciculations may occur and muscle weakness can result in respiratory failure
Sympathomimetic toxidrome Overdose of cocaine, amphetamines, alcohol and sedative hypnotic withdrawal results in similar findings	<ul style="list-style-type: none"> • Elevated vital signs • Tachycardia • Hypertension • Hyperthermia • Agitated delirium is common • Large pupils • Diaphoresis (unless severely dehydrated) • Bowel sounds present <p><i>Note:</i> This toxidrome is usually differentiated from the anticholinergic toxidrome by the presence of marked diaphoresis.</p>
Opiate toxidrome Overdose of heroin and other opiates	<ul style="list-style-type: none"> • Respiratory depression • Depressed mental status • Small pupils • Slight bradycardia (unless hypoxic or hypovolemic) • Prompt response to naloxone hydrochloride
Benzodiazepine/sedative hypnotic toxidrome Overdose of benzodiazepines Some sedative hypnotics	<ul style="list-style-type: none"> • Depressed mental status • Relatively small pupils • Vital signs usually normal • Significant respiratory depression is rare with pure benzodiazepine overdose • Hypotension in large ingestion
Phenothiazine toxidrome Overdose of phenothiazines	<ul style="list-style-type: none"> • Depressed mental status • Small pupils • Do not respond to naloxone hydrochloride
Sedative hypnotic withdrawal	<ul style="list-style-type: none"> • Similar manifestations to alcohol withdrawal, but with a different time course that varies with the half-life of the agent involved

complications. If lavage is considered, assessment of the need to protect the airway and attention to patient position, tube placement, and lavage technique is essential to minimize complications. Lavage may be beneficial in a limited number of situations:

- In the first hour after ingestion
- In life-threatening ingestion (e.g. β -blockers, calcium channel blockers, cyclic antidepressants, theophylline)
- With toxins which cause concretions or pylorospasm.
- Whole bowel irrigation is best used for toxins that are poorly bound to activated charcoal such as iron, lithium or lead, as well as for sustained-release medications (e.g. certain formulations of lithium, theophylline, or calcium channel blockers). Whole bowel irrigation is also useful for removal of ingested drug packets in “body packers” or “stuffers”. This procedure is quite safe in patients who are not vomiting and who have normal gut function.
- Achieved by instilling polyethylene glycol bowel preparation at a rate of 1 to 2 L/ h in adults (500 cc/ h in children) through a nasogastric tube to induce osmotic diarrhea
- Continue until rectal effluent is clear (usually about 6 hours)
- With radiopaque compounds, continue until repeat radiographs are clear.
- Cathartics (e.g. magnesium citrate) are of questionable benefit and probably play a limited role. There may be an argument for adding one dose of cathartic to the initial dose of activated charcoal. However, this is of questionable benefit.

ENHANCED ELIMINATION

- The simplest methods of enhanced elimination are multiple dose activated charcoal (MDAC) and urinary alkalization.
- Due to possible complications, MDAC should be reserved for significant poisonings with agents that form concretions, desorb from activated charcoal in the intestines, or have significant enterohepatic circulation. The MDAC may also be beneficial in very large ingestion where it is impossible to deliver sufficient charcoal in a single dose. In general, it is desirable to administer at least 10 times as much charcoal as toxin on a per weight basis. Examples of toxins that may be suitable for MDAC include large ingestion of theophylline or some anticonvulsants (phenytoin, carbamazepine, valproate, and phenobarbital).
 - Since many preparations of activated charcoal come premixed with sorbitol, the clinician must be aware that repeated doses of MDAC with cathartics with every dose of charcoal may induce severe diarrhea and result in significant dehydration, particularly

in pediatric and geriatric populations. It is recommended that activated charcoal premixed with sorbitol be given every 2nd or 3rd dose. The most efficient and effective way is to monitor cathartic response and administer an activated charcoal/cathartic mixture accordingly.

- Urinary alkalization enhances renal elimination of weak acids such as salicylates, phenobarbital, and chlorpropamide.
 - Urinary alkalization is achieved by infusing bicarbonate-containing fluids: 3 ampules (150 mEq) of sodium bicarbonate to 1 L of D5W and run at 250 cc/ hour (run the IV at 1.5 times of maintenance fluids in children)
 - Achieving urinary alkalization is virtually impossible if there is total body potassium depletion even in the presence of normokalemia on the electrolyte panel. Potassium supplementation is virtually uniformly required
 - Follow urinary pH hourly. Blood pH and electrolytes should be monitored regularly. The frequency of monitoring is dependent upon the severity of the clinical situation
 - The goal is to achieve a urine pH of 8.
- Extracorporeal removal of toxins by hemodialysis or hemoperfusion requires specialized equipment and expertise. Consult clinical toxicologist or poison control center where extracorporeal removal may be necessary.
 - The most common agents requiring extracorporeal removal are the toxic alcohols (ethylene glycol and methanol), lithium, salicylates, and theophylline. Consultation with a nephrologist is recommended when managing a patient with significant toxicity or very high levels following ingestion of one of these agents.
- Other methods of enhanced elimination such as acidification of urine, forced diuresis and continuous gastric suction are not recommended.

ANTIDOTES

Commonly used antidotes, which are useful, are given in Table 4. As there are very few poisonings for which antidotes are available, most of the poisonings are managed with supportive treatment.

- Antidotes are typically given after the patient has been stabilized and the diagnosis has been made.
- In certain cases, prompt administration of antidote is imperative.
- Glucose must be given immediately in hypoglycemia.
- Prompt administration of naloxone may avoid the need for endotracheal intubation in opiate overdose.
- Pyridoxine should be given as soon as possible for seizures associated with isoniazid overdose.

Table 4: Antidote therapy for poisonings

<i>Toxin</i>	<i>Antidote/Pediatric dose</i>
Acetaminophen	N-acetylcysteine, Loading dose: 140 mg orally; Maintenance doses: 70 mg/kg every 4 hours for 17 doses orally
Anticholinergics	Physostigmine salicylate 0.02 mg/kg slow IV infusion over 3-5 minutes titrate to effect
Arsenic	Succimer (DMSA) 10 mg/kg orally 3 times a day British Anti-Lewisite (BAL) (dimercaprol) 3-5 mg/ kg IM every 4-6 hrs only if unable to tolerate succimer
Benzodiazepines	Flumazenil 0.01 mg/ kg IV bolus titrate to effect or total dose of 1-3 mg * It should not be routinely administered in the patient presenting with coma or altered mental status. Reversal of benzodiazepine effect in mixed drug ingestion involving cyclic antidepressants and chloral hydrate may result in seizures or arrhythmias with fatal outcomes
β -blockers	Glucagon 0.15 mg/kg IV bolus, then 0.1 mg/kg/h IV infusion titrate to effect
Calcium channel blockers	Calcium chloride (10%): 0.1-0.2 ml/kg IV bolus, repeat doses and IV infusions commonly required Glucagon: 0.15 mg/kg IV bolus followed by 0.1 mg/kg/h IV infusions (titrate to effect)
Carbamates	Atropine: 0.1 mg/kg IV bolus, repeat doses titrate to effect
Cyanide	Cyanide antidote kit: Sodium nitrite (3%): 0.15-0.33 ml/kg to maximum of 300 mg slow IV infusion followed by sodium thiosulfate: 400 mg/kg up to 12.5 g IV infusion
Digoxin	Digoxin immune antibody fragment: Empiric dosing: 10-20 vials IV bolus for life-threatening toxicity (See package insert for other dosing regimens)
Ethylene glycol, Methanol	Ethanol (10%): Loading dose 10 ml/kg IV or orally followed by maintenance dose 1-2 ml/ kg/ h IV infusion or orally Fomepizole: 15 mg/ kg IV bolus, repeat doses may be necessary
Iron	Desferoxamine: 5-15 mg/ kg/ h IV infusion
Isoniazid	Pyridoxine: 1 g per gram ingested or empiric dosing 75 mg/kg IV bolus up to 5 g
Lead	Succimer (DMSA) (if patient is able to tolerate oral medication orally) 10 mg/kg \times 3 times a day, repeat doses are common BAL (dimercaprol): (only for lead encephalopathy) 3-5 mg/kg IM or 50-75 mg/m ² Calcium disodium EDTA: (Start 4 hrs after BAL ministration) 20-30 mg/ kg diluted in 250 ml IV infusion over 12-24 hours
Methemoglobinemia	Methylene blue: 1-2 mg/ kg slow IV infusion, repeat as needed
Opioids	Naloxone hydrochloride: 0.4-2 mg IV titrated to effect
Organophosphate	Atropine: 0.1 mg/ kg IV bolus, repeat dose titrated to effect Pralidoxime: 20-40 mg/ kg slow IV infusion followed by 5-10 mg/ kg/ h continuous infusion or 20 mg/ kg every 4 hours
Salicylates	Sodium bicarbonate: 150 mEq + 40 mEq KCl in 1L of D5 infused to maintain urine output at 1-2 mL/ kg/ h urine pH 7.5
Tricyclic antidepressants	Sodium bicarbonate: 1-2 mEq/ kg IV bolus, repeat boluses titrate to QRS duration (do not exceed arterial pH 7.55)
Warfarin, Superwarfarins	Fresh frozen plasma: Fresh frozen plasma for life-threatening hemorrhage. Vitamin K1 0.6 mg/kg slow IV infusion, SC or orally

LABORATORY INVESTIGATIONS FOR POISONED PATIENTS

Timely and effective use of the laboratory is important factors in enhancing the value of the tests it provides and for avoiding the expense of inappropriate laboratory testing and treatment. In general, toxicological testing can serve a number of purposes including:

- Confirming a toxic etiology and obviate the need for further diagnostic studies

- Identifying a specific agent
- Assessing the severity of the intoxication
- Predicting the outcome
- Guiding management decisions
- Assessing efficacy of treatment
- Guiding transfer decisions.

It is a good idea to incorporate the principle of “progressive” laboratory investigation in the context of the care of a poisoned patient. In this context, “progressive”

refers to a systematic progression from general laboratory tests to increasingly specific and more sophisticated tests as the clinical situation warrants. For example, the presence of an anion gap on the electrolyte panel together with a documented metabolic acidosis on arterial blood gases would prompt an investigation of ASA, methanol or ethylene glycol as potential etiologic agents. Recognition of each of these toxins requires specific management and ongoing laboratory assessment or therapy that may include transfer to another facility depending upon local resources.

The full spectrum of laboratory tests required for the assessment and management of the poisoned patient is not currently available in most of the hospitals in India. Additionally, prolonged turnaround time may limit the value of the test results in clinical management. In recognition of this reality, a systematic approach to the laboratory investigation of the poisoned patient is essential. The following key concepts are used in laboratory investigations for poisoned patients.

Progressive testing: Progressive testing is a systematic, sequential testing protocol that initially involves the performance of general laboratory tests (e.g. electrolytes, urea, glucose, osmolality), the results from which may then direct the physician to order or the laboratory to perform more sophisticated, specific tests to aid diagnosis (e.g. salicylate, methanol).

Selective testing: Selective testing is specific laboratory testing, either qualitative (e.g. tricyclic antidepressant screen) or quantitative (e.g. acetaminophen), which involves analysis for a particular compound or group of compounds. Selective testing is in contrast to comprehensive testing (e.g. "Tox" or "Drug" screens) which involve simultaneous testing or screening for a larger group of unrelated compounds. Comprehensive testing is usually more sophisticated, labor intensive, and expensive than selective testing. However, not all known compounds can be detected.

DISPOSITION

If adequate health care facilities are not available then one should consider transfer in the following circumstances:

- Inability to stabilize patient
- Deteriorating patient
- Resource limitations including staff, timely diagnostic testing and monitoring equipment
- Clinical judgment suggests a need for transfer
- Inability to provide patient with ongoing maintenance
- Lack of availability of toxin-specific therapy

- Management and disposition of patients following decontamination is toxin and patient specific, occasionally requiring interventions such as dialysis, hemodialysis and hemoperfusion
- Most patients require only minor supportive care and recover without sequel. Patients with uncomplicated acetaminophen ingestion requiring N-acetylcysteine antidote administration can be managed locally
- All patients who have taken a suicidal ingestion require assessment of suicidal risk prior to discharge.

Common Emergency Procedures in Pediatric Office Practice

Suresh Gupta

Pediatricians see lots of emergencies in their office practice which need to be attended immediately. Most of the pediatric training during medical college focuses on medical emergencies only. This article focuses on those common pediatric emergency procedures which they can perform in their office practice.

REMOVAL OF A FOREIGN BODY FROM THE EAR

Core Facts

Common foreign bodies include toy parts, earring parts, hair beads, eraser tips, food items; or stones. It is most common under 8 years of age with peak incidence in the toddler age group 2 to 3 years. Event is usually witnessed by an adult, or alluded to by the child. If witnessed, further trauma to the ear may have occurred as a result of parental attempts to remove it. Indications of ear irrigation or manual removal include foreign body and obstruction of the external canal by cerumen. Minor complications include laceration of the ear canal, perforated tympanic membrane, or a secondary infection. These may occur with the foreign body itself or as a result of removing it. More serious complications include disruption of ossicles, canal hematoma, or facial nerve palsy.

Procedure

Three methods are available for removal of a foreign body, all requiring cooperation or restraint of the child. Because a minor laceration of the ear canal is often unavoidable, the parents should be aware of this complication before the physician undertakes the use of curette or forceps. After removal by any method, it is important to visualize the eardrum and document its condition.

Irrigation

Straighten the ear canal and visualize the foreign body directly with speculum, making sure the tympanic membrane is intact. If the foreign body is sponge or expansible when wet, this method should be avoided. Remove the speculum and irrigate the ear canal by injecting a constant stream of water at body temperature. Use a 20 to 50 ml syringe attached to a flexible intravenous catheter tip. Repeated irrigation may be necessary to provide complete emptying.

Curette

Visualize the foreign body with a speculum, preferably using an operation head otoscope, then very slowly advance the curette just beyond the foreign body as shown, while applying pressure to the foreign body, slowly withdraw the curette until the foreign body is removed.

Forceps

Visualize the foreign body with a speculum and look for a protruding edge of the foreign material. Carefully guide the forceps in the closed position under direct visualization through the speculum. Just a few millimeters from the edge of the foreign body open the forceps and grasp the edge gently. Withdraw the forceps, visualizing the foreign body simultaneously to minimize the chance of a complication.

EVERSION OF THE EYELIDS

Core Facts

Opening the eyelids of an infant or child can be tedious task if not done properly. Eversion of eyelids is required

Fig. 1: Irrigation of ear for removal of foreign body or cerumen

Fig. 2: Use of curette for removal of foreign body or cerumen

for identification of a foreign body or infection; instillation of medications to the conjunctiva; or removal of a foreign body. The minor complications may include mild contusion or ecchymoses (rarely).

Procedure

Have an assistant restrain the infant on the examining table in the supine position with the examining table in the supine position with the arms wrapped around the head. Alternatively, small infants can sit on the lap of a parent who then holds the infant's head still.

Eversion Upper Lid

Upper lid eversion is the more difficult, normally requiring cooperation or restraint, because the examiner needs to use both hands. After restraining the child, grasp the eyelash with distal upper lid between the index finger and thumb. Ask the child to look down at the floor if he or she will cooperate. Draw the eyelid downward and place

Fig. 3: Eversion of upper eyelids

Fig. 4: Eversion of lower eyelid

a clean cotton swab across the superior tarsal margin. In one motion, move the swab slightly downward and pull the eyelid slightly upward. This maneuver should bend the eyelid slightly upward and backward and expose the palpebral surface. To restore the lid to its usual position, lift the swab slightly while maintaining pressure along the upper lid margin and turn the thumb and index finger downward.

Eversion Lower Lid

Place a thumb or finger at the base of the lower lid and gently retract it in a caudal and posterior direction while the child looks upward, while the eyelid is everted, removal of a foreign body can be accomplished. Use a clean cotton

swab and apply it to foreign body to flick it from the conjunctival surface.

IRRIGATION OF THE CONJUNCTIVA

Core Facts

The indication or irrigation of eye includes presence of a foreign body or caustic substance on the corneal or conjunctiva. Concentrated alkalis are found in sparklers and oven/drain cleaners. Damage to the cornea, sclera, or conjunctiva is due to liquefaction necrosis as a result of hydroxyl ions that combine with tissue fatty acids and proteins. Extensive, deep burns, corneal opacification, and conjunctival pallor may develop, and have potentially devastating outcomes. Acids are found in bleach and household cleaners. Damage is due to fatty acid and protein precipitates, causing coagulation necrosis. Burns are more superficial than alkali injuries; however, serious damage is possible if not irrigated immediately. The minor complications of irrigation of the conjunctiva include subconjunctival hemorrhage or corneal abrasion (rare) in a child who is not adequately restrained and conjunctival erythema.

Procedure

Place the child supine over a large sink or pail. Instill 1 to 2 drops of topical ophthalmic anesthetic solution. To restrain an uncooperative child, two assistants are necessary. The person holding the head should wear a gown and may use gauze under each thumb to help keep the eyelids open. Allow bacteriostatic normal saline solution (between room and body temperature) to flow through a set of intravenous tubing. Drip the fluid rapidly into the conjunctival sac. Irrigate for a minimum of 5 minutes for acid using at least 1 liter. Irrigate for 20 minutes for alkali or unknown substance using at least 2 liters. Tap water at

room temperature is an acceptable alternative for irrigation fluid, especially if it can be done immediately. After irrigation, the eye should be carefully examined for corneal and conjunctival integrity, including staining with fluorescein dye.

REMOVAL OF A NASAL FOREIGN BODY

Core Facts

Nasal foreign bodies are most common in 2 to 3-year-old and common foreign bodies include toy parts, beads, insects, paper, and food items. Symptoms depend on how long the object has been lodged in the nasal passages. Usually the child is seen placing an object up the nose that cannot be recovered, or there is a report of pain. Without this, it may remain buried for an unknown amount of time, and is suspected when a purulent, unilateral discharge develops, suggesting a secondary infection. The complications of the procedure may include rhinosinusitis; mucosal laceration; epistaxis; aspiration; and incomplete removal of the foreign body. These are the complications seen with the instrumental removal rather than the positive pressure techniques.

Procedure

Positive Pressure Techniques

Positive pressure techniques are not widely used. When attempted, they may be quite successful, less painful and frightening, and do not require restraints and instrumentation. It is more likely to be successful with an acute foreign body. After vasoconstriction, with use of either mouth-to-mouth by parent, or with AMBU bag and mask applied to mouth of child, occlude the opposite nostril and give a gentle, positive-pressure breath to expel the object. I have personally found these techniques to be

Fig. 5: Irrigation of conjunctiva

Fig. 6: Parent's kiss—a positive pressure technique to remove nasal foreign body

useful and very effective. The pediatricians must try these methods in their clinics before referring the child to otolaryngologists and mostly it will be realized that it can be done without the help of otolaryngologist.

Instrumental Removal

The child should be lying down and restrained. The patient must be kept still during instrumentation of the nose in order to prevent injury to the internal nasal structures. After applying a topical vasoconstrictor-anesthetic agent to shrink the nasal membranes, visualize the interior of the nose with a nasal speculum and a headlight or directed light as shown in figure. Purulent secretions should be gently removed by use of Frazier suction tip until the foreign body is clearly seen. Attempt to extract the object with suction, a hook, or alligator forceps as determined by the size, nature, and position of the object. Figure shows a hook being placed around a round foreign body. Do not push the foreign body into the posterior nasopharynx as the struggling child may aspirate it. The use of irrigation is not recommended because the foreign body may slip posteriorly and be aspirated or hygroscopic foreign bodies may swell and becomes lodged in the nose. After the foreign body has been removed, oral antimicrobial agents may be used in an effort to prevent an infection in the traumatized area.

Fig. 7: Drainage of subungual hematomas

DRAINAGE OF A SUBUNGUAL HEMATOMA

Core Facts

Hematoma formation into the potential space above the nail bed and beneath the nail may result from simple closed minor blunt trauma, nail bed laceration with or without phalanx fracture, or laceration of nail margins. Black, blue, or red discoloration is visible through the nail. The nail is tender to palpation. Distal phalanx fracture may also be present, depending on the force of the trauma. If present, splinting the finger for 5 to 7 days post-trephination will alleviate pain. If a nail bed laceration is present and extends beyond the margins of the nail, removal and repair of the nail bed may be required. The indication for drainage of subungual hematoma is blood under pressure beneath a nail bed, either proximally or distally. The complications due to drainage are uncommon and may include bleeding and infection.

Procedure

Subungual hematomas occur from trauma in the proximal or distal nail bed. Generally the hematoma causes pain that is immediately relieved with drainage. A digital nerve block may be used for anesthesia but is usually not necessary. Making a hole in the nail relieves a hematoma of the proximal nail bed. Restrain the child and digit on a table. Soak the fingertip in povidone-iodine solutions for several

minutes. Hold a scalpel with blade perpendicular to the nail in the center of the hematoma. Puncture the nail by simultaneously applying downward and rotary pressure. Apply pressure sterile gauze to drain the blood for several minutes, and then cover with a sterile dressing.

Alternatively use a microcautery unit or 18-gauge needle or fire-sterilized and heated paper clip and apply gentle persistent controlled pressure to the center of the hematoma perpendicular to the nail until the nail is melted/ punctured. This permits drainage of the hematoma. Guard against puncture or burn of the underlying nail bed. A heated metal wire of paper clip is more rapid and less painful than making a hole with a scalpel. If the hematoma extends to (or close to) the margin of the nail bed, lift the end of the nail with the flat part of a small scissor until the hematoma drains spontaneously.

INCISION AND DRAINAGE OF A PARONYCHIA

Core Facts

A paronychia is a partially circumferential cellulitis or abscess around the base of a nail of the lateral finger or toe tip. A locally contained cellulitis is termed an eponychia, which may resolve spontaneously or progress to invade surrounding tissues. The most common bacteria are *Staphylococcus aureus*. Chronic paronychia may be caused by atypical mycobacteria and fungal infections. Paronychia results from minor trauma, such as nail biting or occasionally a sliver of foreign material, puncturing

Fig. 8: Drainage of paronychia

the eponychium (cuticle), enable bacteria to invade the overlying soft tissues. Infection tends to occur adjacent to the eponychium, where blood supply is most tenuous and recurrent microtrauma is greatest. It then spreads circumferentially around the nail. Advanced paronychia may extend proximally and deep to the nail base. It is the most common hand infection in children. Children are particularly prone to paronychia due to a relatively thin eponychium, finger-sucking and play resulting in local trauma. Chronic paronychia occurs largely in adults whose hands are constantly exposed to moisture, e.g. dishwashers. The indications for drainage of paronychia are the failure of this infection of the soft tissue along the edges of the nail to respond to medical treatment. The complications of procedure of drainage may include bleeding and scar formation.

Procedure

Restrain the child appropriately for age. Prepare the site for the surgical procedure with povidone-iodine solution and cover with sterile disposable drapes. Inject 1 percent lidocaine for a digital block or spray the skin locally with ethyl chloride for anesthesia. Using a No. 11 surgical blade, incise the skin at its junction with the nail. Extend the incision along the base of the nail to permit adequate drainage. If the paronychia is only on one side of the nail bed distal to the cuticle. Dress the wound and instruct the patient to use warm compresses.

REMOVAL OF A SUBUNGUAL SPLINTER

Core Facts

A foreign body located underneath the nail, usually after playing with tree branches or an old wooden structure such as a deck, staircase, etc. Usually an unsuccessful effort has already been made to remove the object. Minor infections such as a subungual abscess or cellulitis may develop if the patient or family delays presentation for care. The minor

Fig. 9: Removal subungual splinter

complication of the procedure may include bleeding and infections if not done properly under aseptic precautions.

Procedure

Restrain the child's hand with the fingers extended and perform a digital block, using 1 or 2 percent lidocaine without epinephrine. Now do sterile preparation of distal phalanx with a povidone-iodine solution. Trim the nail as close to the nail bed as possible using surgical scissors and blunt tweezers or forceps. The further steps depend on the location and size of the foreign body. Foreign body embedded underneath the nail, extending beyond the distal margin of the nail bed. Trap the splinter against the undersurface of the nail using a scalpel tip (number 11 surgical blade) or 25-gauge needle and stroke the splinter toward the distal end of the underside of the nail to dislodge it and dress the wound. If the above method fails or the splinter is embedded underneath the nail, extending close to but not beyond the distal margin of the nail bed. Using blunt dissection with tweezers, elevate the surrounding nail from the nail bed enabling tweezers/forceps removal of the splinter and dress the wound.

If the above method fails or the splinter is deeply embedded and not extending close to the distal margin of the nail bed. Cut a V-shaped wedge in the nail with the proximal point 1 mm proximal to the foreign body and the wide portion at the distal nail edge. Removal of the wedge of nail reveals the entire visible foreign body, leaving the proximal nail intact. Remove the foreign body with a wet sterile gauze or fine tweezers and dress the wound.

REMOVAL OF RINGS

Core Facts

The tight rings can get stuck on the finger and if not removed in time, it can lead to vascular compromise and even gangrene in neglected cases. Children with strangulating ring on a digit are brought to ER only when mother

Fig. 10: String method of ring removal

has failed in removing the ring by lubricating or other domestic methods. There are few simple procedures, which can be conducted in pediatric office practice or ER to remove the strangulating rings on the digit. The complications are few and may include vascular compromise and trauma to digit.

Procedure

String compression of skin: Explain the procedure and position the patient comfortably. Cleanse the area and consider a digital block. Use string or 3-0 silk suture and wrap the suture around the finger, starting at the distal edge of the ring. Continue to wrap the string tightly until it covers the proximal interphalangeal joint. Grasp the ring, and while exerting a back and forth twisting movement, pull the ring over the suture and off the finger. Pull the string around and off the finger at the proximal end to draw the ring off the finger distally. After the ring is off, remove the suture. Cleanse the digit and apply sterile dressing as needed.

String pull: Explain the procedure and position the patient comfortably. Cleanse the area and consider a digital block. Use a string or heavy suture. Place one end of the string under the ring. Pull the string through. Place a small amount of lubricating ointment at the distal end of the ring. Grasp both ends of the suture 5 to 10 cm from the ring. Pull the suture in a circular motion. Continue slipping the suture around the ring as it gradually moves along the finger.

Ring cutting: Often it is preferable to try technique No. 2 or 3 if edema distal to ring is minimal in an attempt to avoid cutting the ring. Explain the procedure as appropriate to the child and parent/ guardian. Position the patient supine or sitting. Cleanse the area with povidone-iodine solution or substitute. Insert the ring cutter guard between

Fig. 11: Re-implantation of completely avulsed permanent tooth

the ring and the finger. Place the blade on the ring. Grasp the handle of the ring cutter and apply pressure while rotating the blade. If the ring is made of hard metal, cutting may be difficult and friction will cause the ring to heat up. If this occurs, stop until the metal cools. After the ring is completely cut through, pull the ring apart manually or with a hemostat and remove from the digit. Occasionally when the child finds the procedure painful, digital block may be necessary to complete ring cutting. Cleanse the digit and apply sterile dressing as necessary. After the ring is removed, cleanse the digit and apply sterile dressing as needed.

REIMPLANTING AN AVULSED PERMANENT TOOTH

Core Facts

Avulsion is complete displacement of the tooth from the supporting socket. Avulsed teeth may be ingested or aspirated, and some effort should be made to find them. Replacement should be done within 30 to 60 minutes to offer the best chance for survival of permanent teeth. Avulsed primary teeth should not be replaced. Since the ED physician does not provide definitive treatment and time is an important factor in outcome.

Procedure

Always handle tooth by its crown and inspect it for fractures. Cleanse tooth by gently swirling it in normal saline solution or a commercial medium. Locate empty socket; for better visualization, lightly suction or swab surrounding area. Position tooth at socket opening and reinsert it

smoothly, applying firm but gently pressure. Hold tooth in place manually or have child bite on gauze pad until dentist arrives. It is important to note that reimplantation is only indicated for an avulsed permanent tooth, not for a deciduous (primary) tooth. The tooth must be reimplanted immediately. Delay reduces the chance of success. If the physician cannot reimplant the tooth, it should be stored in milk. The tooth must always be handled by its crown. The root should never be touched. The dentist should be consulted as soon as the physician is notified about the case.

REDUCTION OF AN INCARCERATED INGUINAL HERNIA

Core Facts

At least 80 percent of incarcerated hernias can be reduced nonoperatively. Emergent operative reduction has a greater morbidity than elective repair. Successful reduction is the goal of the acute care physician. Presence of an inguinal hernia is suggested by a mass in the inguinal area that may extend to the scrotum. In a female the mass appears in the groin or labia majora. Symptoms of incarceration include irritability, poor feeding, abdominal or inguinal pain, and vomiting. Older children report groin discomfort. Signs of incarceration include edema, erythema, tenderness, and/ or bluish discoloration from venous engorgement of the involved area. It may be difficult to distinguish incarceration from strangulation. Strangulated hernia should never be reduced. The perioperative complication rate is 20 to 30 percent in emergent surgery compared to 1 to 2 percent in elective surgical repair of an inguinal hernia. This emphasizes the benefit of nonoperative reduction. The purpose of reduction of incarcerated hernia is to prevent strangulation of incarcerated bowel, ovary, or other organs; and to allow for edema to resolve in order to permit a less hazardous, semi-elective repair of the hernia.

The complications of the manual reduction of incarcerated hernia are not common but may include compression damage of the bowel or other incarcerated organ or tissue; and increased edema with pain.

Procedure

Place the patient supine in a mild Trendelenburg position to decrease edema in the incarcerated tissue. The primary principle of reduction is to reduce the contents of the bowel first, following which the edematous bowel itself may then be coaxed back into the abdominal cavity. To do this, apply bimanual pressure along the entire inguinal canal so that there is uniform pressure on the incarcerated bowel. Begin to apply pressure gently with slightly increased pressure in the distal canal compared to the proximal canal to encourage reduction of intestinal contents into the bowel within the abdomen. Apply a sustained, moderate pressure for up to 5 minutes or until reduction is achieved.

If reduction has not occurred at this point, it may be due to patient discomfort and tensing of the abdominal wall. The patient should then be sedated with 0.1 mg/kg of morphine sulfate and allowed to fall asleep. After a half an hour, reposition the patient gently in Trendelenburg position and apply the same maneuver of sustained pressure along the inguinal canal. If sustained pressure is successful, a gurgling sensation will first be felt as the intestinal contents move back into the intra-abdominal bowel, following which the bowel loop itself may begin to move and finally slide up the inguinal canal and in through the internal ring into the abdomen. When manual reduction, even with sedation, is not successful, it usually is in those situations in which the incarcerated bowel and/or ovary is outside the external ring. Another mass within the inguinal canal, which does not lend itself to ready reduction, is hydrocele, which simulated incarcerated bowel. If reduction is not successful after 5 or 10 minutes' effort with the benefit of sedation, prepare the patient for surgery.

Reduction enmasse of inguinal hernia

Figs 12A and B: Reduction of an incarcerated inguinal hernia

RECTAL PROLAPSE

Core Facts

The prolapse may involve only the mucosa; or may be termed procidentia, which is a complete prolapse of all layers of the rectum. Rectal prolapse is most common in children under age 3 years, in whom it is most often idiopathic. It is hypothesized that this is because these children have recently assumed the erect position, and their musculature is weak, while they begin to take control of defecation. Most children with rectal prolapse have chronic constipation (28%) or acute diarrheal disease (20%, especially shigellosis, *Clostridium difficile*, enterocolitis, etc.). It is idiopathic approximately 20 percent of the time. Cystic fibrosis is identified in nearly 12 percent of cases. Anatomic abnormalities, such as repair of imperforate anus and rectal polyp, or neurologic abnormalities, such as myelomeningocele, account for most of the remainder. Rectal prolapse occurs in 18 to 23 percent of cystic fibrosis patients, often before the definitive diagnosis is made. The diagnosis of rectal prolapse is made by history and physical exam. A history of 1 to 2 centimeter, painless protrusion from the anus during or after defecation is reported, which typically resolves spontaneously. Older children may complain of discomfort or a constant urge to defecate. Blood or a mucosal discharge may be noted from the anus. Manual reduction of rectal prolapse is necessary when it is prolonged, fails to reduce spontaneously or when associated with passive congestion and/

or hemorrhage. Complications of this procedure are extremely rare but occasionally there may be bleeding.

Procedure

In the anxious child (peak age 1-3 years), consider administration of mild sedation (i.e. chloral hydrate) before attempting reduction of a prolapsed rectum. The child should lie prone on his or her knees. Lubricate your gloves with petrolatum (Vaseline) and hold the prolapsed edges with 4 × 4 inch gauze. Then, bimanually apply pressure on alternate sides to reduce the prolapse. Have the patient lie on his or her side afterward. Be sure to address the primary problem.

MANUAL DETORSION OF THE TESTES

Core Facts

Torsion of the testicle is defined as ischemia and infarction of the testicle following twisting of the spermatic cord. Venous obstruction initially leads to venous thrombosis, then impairment of arterial circulation, and eventually infarction. There is essentially no viable testicular function 24 hours after the onset of symptoms. Torsion of the testicle is estimated to occur in 1/4,000 males, and occurs most commonly in males 13 to 25 years of age. Torsion of the testicle occurs more frequently on the left side. There are two peak incidences: Extravaginal torsion occurs primarily within the first few months of life; intravaginal torsion peaks at puberty and may be because of the increase in size and weight that the testicle undergoes at puberty.

The first sign is sudden, severe scrotal pain, often followed by nausea and vomiting and later with erythema and swelling of the scrotum. The patient may have had several brief episodes of testicular pain that spontaneously resolved within the previous few days or weeks. These may represent partial or intermittent torsion. Fever is very uncommon. The testicle often has a horizontal lie, and the cremasteric reflex is absent. Most cases of torsion are idiopathic, although some have an antecedent history of trauma, athletic activity, or sexual activity. So the clinical diagnostic triad of acute scrotal pain, high-riding testis, and absent cremasteric reflex suggests testicular torsion. If there is any suspicion that the patient has torsion of the testicle, obtain a pediatric surgery consult immediately. Always seek urologic consultation for initial assessment and follow-up. Manual detorsion may be successful and of value in first 8 to 12 hours of symptoms. Administer intravenous conscious sedation and/or perform spermatic cord block as indicated.

Torsion almost always occurs with inward or internal rotation-rotate testis within scrotum in outward direction one or two 360 turns. Prompt relief of pain and return to normal position in scrotum suggest successful detorsion. Following successful detorsion, surgical exploration and orchiopexy should proceed as soon as possible.

Figs 13A to C: Reduction of a prolapsed rectum

Fig. 14: Detorsion of testicular torsion

Procedure

The patient requires rapid transport to the ED because delays decrease the testicular survival rate. Proper analgesia may improve the clinical examination, but analgesia or local anesthesia in the ED is not advised unless a decision has been made to go to the operating room immediately, since it will be impossible to determine if the patient has untorted. A urologist should be consulted before giving any pain medicine. The patient should be NPO for emergent surgery. Manual detorting the testicle may be tried in the ED, particularly if duration has been 4 to 6 hours or more since the onset of pain and there is a chance of regaining viability, or the patient needs to be transferred to another facility, and there will be a delay in surgery. Manual detorsion may be successful and of value in first 8 to 12 hours of symptoms. Administer intravenous conscious sedation and/or perform spermatic cord block as indicated. Most torsions rotate the testicle medially. Therefore, twisting the testicle from medial to lateral will return the testicle to a normal anatomic position and permits blood flow. When standing at the patient's feet, twist the left testicle clockwise and the right testicle counterclockwise, e.g. "opening a book." This maneuver should only be attempted once. Do not continue to twist the testicle in an effort to untort it. Even if the procedure is successful, the urologist should be consulted for further management. Detorsion is only a time buying procedure before the patients arrive in a facility which can handle the situation.

PARAPHIMOSIS REDUCTION

Core Facts

Paraphimosis results from a constricted ring of retracted foreskin causes obstruction of the arterial, venous and lymphatic flow. This in turn leads to edema of the foreskin and underlying glans. The usual cause is failure to reduce the foreskin back over the glans after manually retracting it for penile cleaning or catheterization. The foreskin is retracted,

engorged, edematous, and usually very tender. The entrapped prepuce can be erythematous; rarely cyanotic and/or necrotic after prolonged entrapment. The glans may also become edematous and tender, usually inferior or immediately adjacent to the constricted foreskin. There is usually a clear margin between the swollen retracted foreskin and the proximal glans of the penis. The penis is flaccid proximal to the level of foreskin engorgement. If the proximal phallus is more diffusely edematous and tender, an infectious etiology (balanoposthitis, which is a local cellulitis) becomes more likely. Parents of uncircumcised boys should be cautioned not to forcibly retract the foreskin. Uncircumcised boys with retractable foreskin should be taught to return it to the normal position after cleaning.

Procedure

Pediatricians in the pediatric emergency room or in pediatric offices can reduce most of the paraphimosis. Prompt reduction of paraphimosis obviates later difficult reduction of the extremely swollen foreskin and glans penis. Prolonged and painful attempts at reduction must be avoided. With more difficult cases urological consultation should be sought early. Following is a simple stepwise approach for paraphimosis reduction.

Step 1: If necessary, dorsal penile nerve block can be performed in 3 ways:

For single injection nerve block, first palpate the pubic symphysis and then vertically advance a 22-gauge needle at the base of the penis until it comes in contact with the inferior border of the symphysis pubis. Then, withdraw the needle slightly and advance it parallel to the pubic symphysis until there is a loss of resistance, indicating penetration of Buck's fascia. This usually occurs approximately 5 mm beyond the anterior border of the pubic symphysis. A single injection of lidocaine or bupivacaine may be given, after ensuring that the needle is not in a blood vessel. For bilateral injection nerve block, follow the same steps as above until penetration of Buck's fascia.

Fig. 15: Manual reduction of paraphimosis

Instill 1 percent lidocaine on either side of the midline at 10 o'clock and 2 o'clock positions. Alternatively one can infiltrate lidocaine subcutaneous in a concentric ring around the base of the penis. Complications of nerve blocks include:

- i. Ischemia if epinephrine is used,
- ii. Hematoma,
- iii. Intravascular injection

Step 2: Manual compression: Encircle the foreskin with a gloved hand and apply pressure for 5 to 10 minutes.

Step 3: Manual reduction: Using both hands, place the index finger at the dorsal aspect of the foreskin, the thumbs at the tip of the penis, and the other fingers on the ventral aspect of the foreskin. Then push the glans inward with the thumbs while applying traction to the foreskin to pull it over the glans.

Alternative Methods

Place the entire palm of the hand around the foreskin and apply traction while pushing the glans in with the thumb of the other hand. Fill half of size 8 latex surgical gloves with ice and water. Push in the thumb of the glove. Apply lubricant to the penis. Place the penis inside the thumb of the glove. This step helps reduce edema and causes vasoconstriction. After this step, re-attempt manual reduction as outlined in step 3.

Babcock clamp method: If manual reduction in step 3 fails, hold the phimotic ring of foreskin with 6 to 8 Babcock clamps and apply traction slowly pulling the foreskin slowly over the glans. Do not use serrated (Allis) clamps. Complications may include tearing of the foreskin. In this case, urology should be consulted to perform operative dorsal slit of the foreskin.

Dorsal slit of the foreskin: If the Babcock clamp method fails, this may be attempted in the ED, if urology is not available for any reason. Use 1 percent lidocaine local infiltration in a line at the 12 o'clock position along the constricted ring.

Begin infiltrating 0.5 cm proximal to the constriction making a line 0.5 cm distal to it. Then make a small circumcision along the line of anesthetic infiltration, passing through the skin, subcutaneous layer, and the constricting ring. The proximal and distal edges of this incision should be brought together with 4.0 chromic sutures using a continuous suture technique. Bleeding is the most common complication of manual reduction, and may be treated with a compression dressing. One can consider emergency circumcision if all other methods fails.

ZIPPER ENTRAPMENT INJURIES

Core Facts

The key to treatment of zipper entrapment is to avoid further manipulation of the zipper. Take the fastening device apart by cutting the median bar. Zipper injuries occur most commonly when the uncircumcised male zips up his pants too quickly and entraps the foreskin of the penis in the zipper mechanism. Children with foreskin entrapment are frequently in a great deal of pain and are very anxious. Two types of zipper entrapment are generally seen: a) The most common type presents with the foreskin stuck in the moveable part of the zipper, b) Less commonly, the foreskin may be caught between the teeth of the zipper, the moveable part having been pulled beyond the foreskin. The foreskin may be caught between the teeth of the zipper or is frequently wedged between the engaged zipper teeth and the casing of the slide fastener. The foreskin may be swollen.

Procedure

- In most cases, no local anesthetic is necessary to remove the zipper as it is a painless procedure. However, in the highly anxious or uncooperative child, a restraint device, local infiltration with Xylocaine®, or sedation may be required.

Fig. 16: Release of foreskin during zipper injuries

- In the situation where the foreskin is entrapped in the zipper sliding mechanism, the median bar of the zipper can be cut with a wire or bone cutter. This will permit the two halves of the zipper to fall apart, releasing the entrapped skin.
- In the less common situation where the entrapment of foreskin is between the teeth of the zipper alone, simply cutting across the zipper with a scissors below the entrapment will allow the teeth to separate and release the foreskin.

PULLED ELBOW OR NURSEMAID ELBOW

Core Facts

It is one of the most common subluxation seen in the children. The most common mechanism is a fall on an outstretched hand. Subluxation of the radial head occurs after a pull on the forearm in a young toddler, mainly 1 to 3 years of age. In many cases, there is no clear or recalled history of a pull. On examination, the forearm is held pronated, with partial flexion at the elbow. There is no deformity or ecchymosis, but there may be tenderness at the wrist, elbow or shoulder. Reduction of the subluxation, which may be done without radiographic studies before or after, is curative. Technique is simple and can be easily performed by pediatricians in their offices.

Procedure

The reduction of pulled elbow can be done without any sedation analgesia by the pediatricians in their offices. The diagnosis is clinical and radiography is not needed to confirm the diagnosis. Make the child to sit in the lap of mother with elbow held posteriorly, to prevent the child from running away during the reduction. The child's hand is grasped in a hand-shaking gesture, and then rapidly rotated externally and flexed simultaneously. There is often

a palpable "click" or "pop" as the radial head reduces, accompanied by a sharp cry from the infant. If a pop is not felt, the maneuver may be repeated once. If still unsuccessful, a radiograph of the forearm should be obtained. If there has been a palpable pop, the child should have a return to normal movement in 5 to 15 minutes. If unsuccessful, and subsequent radiographs are negative, the arm should be placed in a sling, and parents instructed to follow-up the next day with their primary care provider or orthopedist.

Pain and Palliative Care for the Pediatric Patient

Veronique Dinand, Tulika Seth

BACKGROUND

A growing number of children live with chronic life-limiting conditions, leading to impaired quality of life. Life-threatening diseases in childhood such as neurologic, rheumatological and genetic disorders, cancers and acquired immunodeficiency syndrome (AIDS), require palliative care. With steady improvement in the management of these diseases over the years, longer survival has been achieved in many of these conditions, but quality of life remains a major challenge. The vital role of pain management and palliative care in these children has received increased attention and importance.

Palliative care is the art and science of patient- and family-centered care aimed at attending to suffering, promoting healing and improving quality of life. It provides relief of physical, emotional, social and spiritual suffering. Palliation begins when illness is diagnosed and continues until cure or death.

PALLIATIVE MODEL OF CARE

Palliative care is an interdisciplinary care that aims to relieve suffering and improve quality of life for patients with advanced illness and their families. The WHO defined quality of life as “Individuals perception of their position in life in the context of the culture, value systems in which they live; their goals, expectations, standards, and concerns”.¹ Health-related quality of life is related to physical function and mobility, cognitive function, self-care, emotional status, sensory function and pain.² The primary goal in palliative care is relief of suffering, whereas the primary goal in modern medicine is to cure, and death is seen as an ultimate failure. In a palliative model of care, enabling a patient to live fully and comfortably until death

is a success. The palliative model of care recognizes the importance of cure as well as control and relief of suffering. Thus palliative care is not restricted to ‘End of Life’ care and is offered simultaneously with all other appropriate medical treatment, from the time of initial diagnosis. All four fields of palliative care, i.e. support, comfort, dignity and team approach, can be established more easily in pediatric practice than in adults. Palliative care is provided both within specific structures such as the hospital (palliative care unit, intensive care unit, pediatric department, pediatric oncology unit) or palliative care hospice and outside through home visits.

Palliative care is not doctor-centered but involves allied health professionals: physicians, social workers, palliative care-trained nurses, psychologists, occupational therapists and child-life specialists. All have an equally important part in an interdisciplinary rather than multidisciplinary approach. Adequate support requires a holistic approach, treating the whole person in its physical, emotional, spiritual and social dimensions.³

COMMUNICATION

Collaborative communication between health care takers and the patient and relatives is fundamental at all points of patient care: initial diagnosis, curative treatment and palliative care.⁴ Collaborative communication involves the family. It is especially delicate when faced with the issue of communicating bad news. Communicating the truth builds the physician-patient relationship, fosters collaboration, permits the family to plan and cope (Table 1). When language is a barrier, it is important to involve a skilled translator who is used to medical terminologies and is not a part of the patient’s family.

Table 1: The six-step protocol to reveal bad news (adapted from Robert Buckman⁷)

<i>Steps</i>	<i>Do's</i>	<i>Don'ts</i>
1. Getting ready	<ul style="list-style-type: none"> Plan what to say Conducive environment (proper room, tissues, etc.) Adequate time, blocking at least 30-60 minutes Body language: sit down, eyes at their level Ask who else parents would like to be present 	<ul style="list-style-type: none"> No interruptions by cell phone/pager Body language: don't look at watch Avoid family members as primary translators
2. Establish what the parents know	<ul style="list-style-type: none"> "What are you expecting to happen? How specific do you want me to be?" Assess ability to comprehend bad news Reschedule if they are unprepared 	<ul style="list-style-type: none"> Do not assume parents understand about the disease, prognosis or treatment
3. Establish how much they want to know	<ul style="list-style-type: none"> If they decline to know, say "this is what I have to do" If the parents don't want the child to be told, ask why Wait for their informed consent to tell the child: "We will talk to the child together" 	<ul style="list-style-type: none"> Don't allow one parent to hide the diagnosis from the other Don't lie to the child
4. Sharing the information	<ul style="list-style-type: none"> Say it in small pieces Pause frequently, check for understanding. Allow silence for them to reflect or dialogue Use clear words to make them understand diagnosis and prognosis (e.g. "cancer", "HIV", "death") You may acknowledge that you are sorry (e.g. "this must be very difficult for you") 	<ul style="list-style-type: none"> Avoid medical jargon Avoid euphemisms about death and dying (e.g. "terminal," "critical," "not doing well," "unresponsive to treatment") Avoid "I know how you feel" because no one can
5. Responding to the feelings of the patient and his/her family	<ul style="list-style-type: none"> Broad range of reactions: affective (tears, anger, sadness), cognitive (denial, blame, guilt) or basic psycho-physiological (flight to fight) Listen, use non-verbal communication (holding hands) 	<ul style="list-style-type: none"> Do not be cold and distant Do not be afraid to show emotion or distress
6. Planning, follow-up	<ul style="list-style-type: none"> Explain further plan of care Goal setting: treatment objectives and expectations There is hope for a pain-free and symptom-free life Emphasize the quality of life 	<ul style="list-style-type: none"> Don't say "there is no hope"

The physician reveals the truth to the patient's family first, giving them some time (a day or more) to face and comprehend the situation and then reveal it to the child. Using an age-appropriate way of revealing the illness, a child as young as 7-year-old may be told about the prognosis truthfully and tactfully. In the Indian scenario parents are unwilling to discuss or inform even older children about the diagnosis of a life threatening disease and poor prognosis.⁵ However, many children and teenager wish to understand their underlying disease and prognosis, as well as to take part in therapeutic decisions. All children intuitively know about the outcome of their illness.⁶ Honesty with the child promotes trust. Building trust may take time, but it is essential in the management of children suffering from chronic conditions.

PAIN MANAGEMENT

In the developed world, the major sources of pain in children are due to diagnostic and therapeutic procedures. In the developing world, most chronic pain is disease-related and most children are under-treated for pain. The multidimensional character of pain, i.e. psychological, social, spiritual and physical, requires a multidimensional approach. Determining the type of pain is important since response to treatment will depend on the type of pain.

Types of Pain

- Nociceptive or physiological pain is caused by the stimulation of sensory receptors (nociceptors) in the tissues, with normal nerve system. There are two types of nociceptive pain:

1. Somatic pain is usually well localized to the skin and superficial structures
 2. Visceral pain is usually difficult to localize
- Neuropathic pain is caused by peripheral or central nervous system injury. The injured nerves either react abnormally to stimuli or discharge spontaneously, causing dysesthesia (described as burning, tingling) or shooting pain (described as an electric shock). Neuropathic pain is less responsive to non-opioid and opioid analgesics and responds better to adjuvant analgesics, particularly anticonvulsants.
 - Sympathetic pain is caused by damage to sympathetic nerves. It is characterized by burning pain, increased sensitivity and sympathetic dysfunction (erythema, pallor, edema, sweating, trophic changes). It responds poorly to analgesics, but responds well to regional sympathetic nerve block.
 - Psychogenic pain in which no physical basis can be found to explain the pain. Since all chronic physical pain is associated with some degree of psychological distress, primary treatment of the cause of physical pain is fundamental. Psychological pain requires psychological therapies.

Pain Assessment

Pain assessment starts with a complete evaluation.

- Assess the child: QUESTT
 - Q – Question the child
 - U – Use pain rating scales
 - E – Evaluate child's behavior
 - S – Secure parent's involvement

T – Take cause of pain into account

T – Take earliest action

- Conduct physical examination
- Determine primary cause of pain
- Evaluate secondary causes (environmental and internal)
- Develop treatment plan: Analgesic drugs and non-analgesic therapies
- Implement Plan
- Assess regularly and revise plan as necessary

Documentation of pain score with the time of observation should form a part of routine pediatric charting. There are multiple pain assessment scales adapted to diverse age groups.⁸ Observation methods based on behavioral response are used to assess pain in preverbal and nonverbal children. The FLACC Behavioral Pain Assessment Scale (Table 2) has been validated in children aged 2 to 7 years.⁹

Self-report pain scales facilitate communication from verbal children about pain, such as the Wong Faces Pain Scale, validated in children above 4 years (Fig. 1)^{10, 11} and the Visual Analogue Scale (Fig. 2). Always remember that pain is what the child says it is.

Analgesic Therapy

Drug treatment is the main stay in pain management. Placebo plays no role in the treatment of chronic pain in palliative care. Analgesic therapies should be combined with appropriate psychosocial, physical and supportive approaches, since pain is multidimensional. The 3-step WHO analgesic ladder (Fig. 3) forms the basis of pain control in palliative care.

Table 2: FLACC behavioral pain assessment scale (face legs activity cry consolability scale)⁹

FLACC		Scoring		
Score	Indicators	0	1	2
0: Relaxed and comfortable	Face	No particular expression or smile	Occasional grimace or frown; withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
1-3: Mild discomfort	Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking or legs drawn up
4-6: Moderate pain	Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid or jerking
7-10: Severe discomfort or pain or both	Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs; frequent complaints
	Consolability	Content, relaxed	Reassured by occasional touching, hugging or being talked to; distractable	Difficult to console or comfort

Instructions for Usage

In patients who are awake: observe for 1-5 min or longer. Observe legs and body uncovered. Reposition patient or observe activity. Assess the body for tenseness and tone. Initiate consoling interventions if needed.

In patients who are asleep: observe for 5 min or longer. Observe legs and body uncovered. If possible, reposition patient. Touch the body and assess for tenseness and tone.

Fig. 1: Pain assessment scale in children over 4 years of age – The Wong Baker faces pain rating scale (with permission, from <http://www.wongbakerfaces.org>)

Instructions for Usage

Explain to the child that each face is for a person who has no pain (hurt), or some, or a lot of pain.

"Face 0 doesn't hurt at all. Face 2 hurts just a little bit. Face 4 hurts a little more. Face 6 hurts even more. Face 8 hurts a whole lot. Face 10 hurts as much as you can imagine, although you don't have to be crying to have this worst pain." Ask the child to choose the face that best describes how much pain he/she has.

Fig. 2: Pain assessment scale in teenagers—visual analogue pain scale

Instructions for Usage

The child should be able to verbalize a number, > 9 years old.

Ask the child: "On a scale of 0 to 10, with 0 meaning 'no pain' and 10 meaning the worst pain you can imagine, how much do you hurt right now?"

Various degrees of pain are equivalent to 0-no pain, 2-annoying, 4-uncomfortable, 6-dreadful, 8-horrible and 10-unbearable pain.

In case of chronic pain, the medical person assessing pain should have knowledge of the patient's baseline level of pain to appreciate efficacy of analgesic therapy.

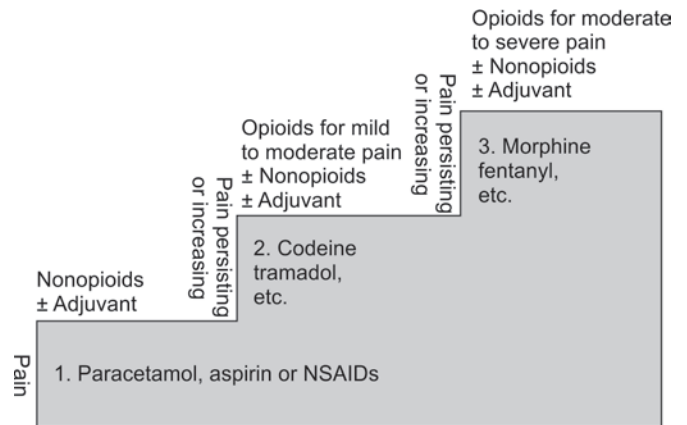

Fig. 3: The 3-step WHO analgesic ladder

Whenever one drug provides no relief, then a drug combination or a change of drug is required. Analgesic therapy is given "by the ladder, by the clock, by the appropriate route, by the child", i.e. choice of analgesics guided by the analgesic ladder; analgesics given at a regular schedule, not as required; choosing the least invasive route of administration, easily accepted by the child; analgesic therapy individualized to the child (Table 3).

Mild to Moderate Pain

Mild pain is treated by nonopioid analgesics: paracetamol and nonsteroidal antiinflammatory drugs (NSAIDs). Nonsteroidal anti-inflammatory drugs are contraindicated in children with thrombocytopenia. Weak opioids (codeine and dextropropoxyphene) can be added to nonopioid analgesics at the second step of the analgesic ladder, i.e. mild to moderate pain. Codeine is used at twice the antitussive dose. If pain control is insufficient, codeine plus paracetamol are a good option.

Severe Pain

Strong opioids are required for moderate to severe pain, in association with step 1 nonopioids. Since narcotics are prohibited drugs, they can be dispensed only with a license. A special prescription is required on an official form of prescription (form DD7) provided by the chemist, or on the doctor's letterhead, with his/her State Medical Council number and stamp. The prescription should mention the name, address and description of the person to whom the prescription is issued, so as to reduce the risk of misuse.

Although India is a major opium exporting country, there is minimal access to opioids, due to regulatory and opioid availability issues.¹² Efforts at improvement of stringent laws on opioid use led to Amended Narcotic Rules (1999), which has approved "Recognized Medical Institutions" providing palliative care and allots them an opioid quota. Few chemists provide narcotics in metropolitan cities. Opioids that are available in India are codeine,

Table 3: Analgesic medications in children above 6 months of age

<i>Drug classification</i>	<i>Analgesic</i>	<i>Dose</i>	<i>Formulation</i>
Non-opioid analgesics	Paracetamol	10–15 mg/kg po q6h	Tab 500 mg, Syrup 125 mg/5 ml, Drops 100 mg/ml, Suppositories 80 mg, 125 mg, 250 mg
	Ibuprofen	10–20 mg/kg po q6h	Tab 200 mg, 400 mg, 600 mg, syrup 100 mg/5 ml
	Diclofenac	1 mg/kg po q8h to q12h	Tab 25 mg, 50 mg
	Naproxen	10 mg/kg po q12h	Tab 250 mg, 500 mg
Weak opioids	Codein	Start at 0.5 mg/kg, increase to 1–3 mg/kg q4h	Linctus codein syrup (codein-10 mg/5 ml)
	Tramadol	6–12 yr: 1 tab q6h >12 yr: 2 tab q6h	Tab tramadol 37.5 mg + Paracetamol 325 mg
	Dextropropoxyphene	1–2 mg/kg q12h	Tab 65 mg + Paracetamol 400 mg
Strong opioids	Fentanyl	IV bolus 1–2 µg/kg IV infusion 1–3 µg/kg/hr Transcutaneous	Inj 50 µg/ml, 100 µg/2 ml Transdermal patch 25 µg/h, 50 µg/h, 75 µg/h, 100 µg/h for 24h or 72 h
	Morphine	0.15–0.3 mg/kg po (opioid-naïve child) ^a 30–60 µg/kg/hr SC	Tab ^b 5 mg, 10 mg, 20 mg, 30 mg, 60 mg CR ^c Tab 10 mg, 30 mg, 60 mg Inj 15 mg
	Buprenorphine	IV/IM 3–6 mg/kg Sublingual 5–7 mg/kg	Inj 0.3 mg/ml, 0.6 mg/2 ml SL Tab 0.2 mg
	Pethidine ^d	IV 0.5–1 mg/kg	Pethidine inj 50 mg/1 ml, 100 mg/2 ml

Note: (a) 0.05–0.1 mg/kg in infants <6 months. (b) Immediate release. (c) Controlled release. (d) Never as continuous infusion (neurotoxicity)

Table 4: Opioid equianalgesic doses

<i>Opioid</i>	<i>Equianalgesic dose (mg)</i>	
	<i>Intravenous</i>	<i>Oral</i>
Morphine	10	30
Fentanyl	0.1–0.2	Not available

pethidine, morphine, fentanyl and tramadol. Substitution of an opioid for another in case of poor pain control or significant side effects may result in improved analgesia and fewer adverse effects. Fentanyl has rapid onset and short duration of action. It is the opioid of choice in hepatorenal dysfunction. Buprenorphine, with its longer duration of action than morphine, is both safe and effective. When switching to an alternative opioid, use equianalgesic doses (Table 4).¹³ When substituting intravenous fentanyl with oral morphine, fentanyl should be titrated only after starting the latter.

Oral morphine is preferred route for patients who require morphine chronically, e.g. children with progressive cancer. Short acting morphine elixir (currently not available in India) or 5 mg tablets are used initially; tablets may be crushed and mixed with 5 ml of any beverage for administration to young children. The dose is titrated to attain pain control, increasing by 50 percent everyday till total pain control, after which the patient is switched to

12 hourly slow release morphine tablets (MST preparation), available through the IAPC. Opioid-tolerant children require dose escalation at the end of life, with no maximum acceptable dose to control severe oncological pain. Fentanyl transdermal patches of various strengths offer a 1-day or 3-day pain relief with easy administration (Table 4). Once-daily morphine (MXT preparation) and fentanyl oral preparation are not available in India.

Expected side effects of opioids include nausea/vomiting and constipation by reducing gastrointestinal motility. Thus antiemetics and laxatives are prescribed routinely for the prevention of constipation (Table 5). Itching is another common complication, usually tackled with oral anti-histaminics and skin emollients provide some relief. Contrary to cetirizine and hydroxyzine hydrochloride, loratadine leads to minimal sedation. However, intractable itching may require a change of opioid, e.g. fentanyl, or continuous morphine infusion along with low-dose infusion of naloxone at 1–2 µg/kg/h, feasible only in hospital setting.

Opioid-induced respiratory depression can only occur in case of accidentally high dose of or sudden hepatic or kidney failure in children. Hypotension, bronchospasm and chest wall rigidity are never seen with oral morphine. Somnolence is common, and judicious balance between a pain-free and over-sedated child needs to be found in concert with the family. In case of over-sedation, switching

Table 5: Adjunctive therapy to opioid prescription

Indication	Drug classification	Drug	Dose	Formulation
Prevention of constipation	Softening agent	Lactulose	5–15 mL q8h Upto 1 ml/kg per dose	Syrup 10 g/15 ml
Nausea	Dopamine antagonist	Domperidone	0.2–0.4 mg/kg q4h to q8h	Tablet 5 mg, 10 mg Syrup 5 mg/5 ml Drops 10 mg/ml
Excessive sedation	Piperidine	Methylphenidate	0.3–2 mg/kg/day Start with 5 mg before breakfast and lunch and increase	Ritalin® Tab 5 mg, 10 mg, 20 mg Ritalin LA® cap 20 mg, 30 mg, 40 mg Concerta® tab 18 mg, 27 mg, 36 mg
Itching	Antihistaminic	Cetirizine	2–6 yrs: 2.5 mg BD or 5 mg OD >6 yrs: 5 mg BD or 5 mg OD	Syrup 5 mg/5 ml Tab 5 mg, 10 mg
		Hydroxyzine	0.5 mg/kg q6h	Syrup 10 mg/5 ml, Drops 6 mg/ml Tab 10 mg
		Loratidine	2–6 yrs: 2.5 mg OD 6–12 yrs: 5 mg >12 yrs: 10 mg OD	Syrup 5 mg/5 ml Tab 10 mg
Opioid over-dose		Naloxone	0.1 mg/kg per dose IV. Max 2 mg. Repeat after 2-3 min if needed	Inj 0.02 mg/ml Inj 0.4 mg/ml

Table 6: Adjuvant analgesic medications in children

Indication	Drug classification	Drug	Dose	Formulation
Neuropathic pain	Anticonvulsant	Gabapentin	5 mg/kg po at bed time, increase q12h than q8h till effective analgesia (max 60 mg/kg/day)	Cap 300 mg, 400 mg
		Carbamazepine	3–10 mg/kg q8h	Syr 100 mg/5 ml Tab 100 mg, 200 mg, 400 mg
		Clonazepam	0.01–0.03 mg/kg/day q8h–q12h. Max dose 0.2 mg/kg/day	Tab 0.25 mg, 0.5 mg, 1 mg, 2 mg
Anxiety, muscle spasm	Benzodiazepine	Lorazepam	0.025–0.05 mg/kg q6h, max 2 mg per dose	Tablet 1 mg, 2 mg
Depression	Tricyclic antidepressant	Imipramine	0.5 mg/kg q8h initially. Increase by 1–1.5 mg/kg/day (maximum 5 mg/kg/day)	Tab 25 mg Cap 25 mg, 75 mg

to another drug is useful. Addition of methylphenidate is an alternative; however, this expensive psychostimulant is a controlled drug that can only be prescribed by psychiatrists.

Adjuvant Analgesic Therapy

Adjuvant therapy to analgesics includes antidepressant, anticonvulsants, corticosteroids and muscle relaxants (Table 6). Their judicious use is adjusted to the type and cause of pain (Table 7).

Alongside pharmacological measures, non-pharmacological analgesic measures are very useful to reduce pain. They include behavioral, psychological, physical and

cognitive approaches. Behavioral measures are relaxation therapy, deep breathing exercises, etc. Psychological support is needed for both children and parents, with particular need to relieve anxiety. Physical approach to pain may be occupational therapy, acupuncture, massages, etc. Cognitive interventions, such as imagining an enjoyable item or experience, help focus the attention to other thoughts than discomfort and pain.¹⁴

Interventional Pain Management

When pain is not relieved by the 3-step WHO ladder, patients should be referred to an interventional pain management physician. Intractable pain described as an

Table 7: Types of pain and management in children with cancer

<i>Type of pain</i>	<i>Cause</i>	<i>Management</i>
Nociceptive pain	Soft tissue	Nonopioid \pm opioid analgesics
	Bone	Nonopioid \pm opioid analgesics Steroids
	Visceral	Nonopioid \pm opioid analgesics
Neuropathic pain	Nerve compression	Steroids \pm Opioid analgesics
	Shooting/lancinating pain (Nerve infiltration/damage)	Opioids Anticonvulsants \pm Antidepressants
Sympathetic pain		Sympathetic nerve block
Other pain	Headache caused by intracranial tumor	Steroids
	Muscle spasm	Muscle relaxant
		Nonpharmacological analgesic measures

electric shock, stabbing or burning, suggests persistent pain caused by damage to the peripheral or central nervous system. In addition, these patients often show signs of paralysis and pain hypersensitivity. Neurolytic block or epidural/intrathecal infusion of morphine is indicated. Use of fixed program devices such as patient-controlled analgesia infusion pump for intrathecal drug delivery is ideal and should ideally be used when life expectancy is greater than 6 months.

MANAGEMENT OF OTHER SYMPTOMS

Nausea and Vomiting

Pharmacological Measures

An initial evaluation is required to identify the underlying cause of vomiting, since treatment of the cause may be more effective than antiemetics alone. Common causes are raised intracranial pressure, gastritis, opioids, partial or complete bowel obstruction. Phenothiazines, lorazepam, or dexamethasone may be effective in treating nausea and vomiting.

Serotonin antagonists (e.g. ondansetron, metoclopramide) are very good antiemetics even for non-chemotherapy related vomiting, such as opioid-induced nausea. Diphenhydramine (Benadryl®) along with metoclopramide is an effective combination. Metoclopramide at low dose enhances motility. Anxiety exacerbates nausea and vomiting and should be addressed. Anticipatory nausea is effectively managed with anxiolytic drugs.

Nonpharmacological Measures

Nonpharmacological measures to control nausea and vomiting include keeping the child in a calm environment, away from the smell of food, and giving small feeds frequently.

Nutrition

Assessing the Cause for not Eating

A child may not eat because he or she is not hungry, or because of other causes prevent the hungry child from

eating. A child with a minimum of appetite only needs to be helped to feed and drink. An anorexic child with short prognosis should not be forced to feed, since it would only cause suffering but without prolonging life.¹⁵ Treatable causes of poor feeding, such as mouth ulcers, oral thrush, dysphagia, nausea and vomiting, severe constipation, dyspnea, pain, chronic infections, etc. need proper management, and will often result in an increased appetite. Drugs causing anorexia should be changed e.g. opioids, metronidazole, etc.

Oral Feeding

Enteral feeding should be encouraged as much as possible, even if the child is not able to take by mouth. As long as possible, the child should take orally nutrient-rich foods and fluids providing a well-balanced diet, within the child's favourite dishes and preferences with easily tolerated food and drink. If preparing or getting the request food will take more than an hour, the child is likely to no longer want it. The child should not be forced, but may want to eat it at the next meal or snack. Attendants should also be ready to adjust to changes in taste.

Being flexible with timings is important, while trying to stick to normal family mealtime habits as much as possible helps maintain a near-normal life. For instance, three meals and three snacks a day encourages feeding in a child with poor appetite. These small frequent feeds are helpful to complement small meals, with high-calorie and high-protein food and homemade drinks and shakes. Commercial liquid nutritional supplements can be advised when food is refused. If only liquid diet is tolerated, one may vary the type of liquids, e.g. soups, juices, curd and coconut water. Daily supplementation with vitamin C, pyridoxine, thiamine, the fat-soluble, D, E, K and folic acid are easily provided with a multivitamin preparation.

Tube Feeding

If oral intake does not meet calorie and nutrient requirements, feeding by nasogastric tube can be easily managed

by mothers at home, with minimal training. Initially, tube feed can be tried at night while sleeping, so that the child may eat during the day. As anorexia progresses, feeds are given every 3 to 4 hours. Regular mouth rinsing and brushing is still required while on tube feed. Feeds may consist of milk or home-made food mixed and liquefied. Tube feeding by gastrostomy or jejunostomy is justified in case of upper gastrointestinal obstruction. Caregivers need to be educated about daily skin care of the gastrostomy or jejunostomy site with antibacterial soap and bolus feeding.

Parenteral nutrition is rarely indicated in children with intractable vomiting, such as intestinal obstruction or uncontrolled vomiting or diarrhea. In India, parenteral nutrition can only be given in hospital or hospice setting.

Cachexia

Cancer-related or AIDS-related cachexia is characterized by lack of appetite, weight loss due to fat and skeletal muscle wasting, anemia, fatigue and edema. It can only be improved with treatment of the underlying condition leading to the release of cytokines responsible for this syndrome. Cachexia usually improves with antiretroviral therapy in case of AIDS, but this is usually not possible in the case of terminal cancer. Parents need to be told that it is not associated with hunger or thirst, and does not improve with forced feeding or hydration.

Cyproheptidin and megestrol acetate are commonly used to improve appetite and increase weight in cancer-associated and AIDS-associated anorexia, cachexia or unexplained weight loss. Significant weight gain can be obtained with cyproheptidin (0.25–0.5 mg/kg/day in 2 or 3 divided doses) and megestrol acetate (7.5–10 mg/kg/day in divided doses) in children with cancer-related and HIV-related cachexia.¹⁶ However, caution is required, with possibly glucocorticoid stress coverage, since a transitory or severe secondary adrenal suppression may occur.¹⁷

Constipation

Inactivity, decreased mobility, poor oral intake and drugs predispose to constipation. Such common drugs include opioids, antidiarrheals, anticholinergics drugs, antispasmodics, 5-HT₃ receptor antagonists, vincristine. Other causes may be related to complications of the underlying illness itself (e.g. bowel obstruction, involvement of the sacral nerve roots, etc.).

Constipation may be prevented by increased food intake, dietary fiber and fluid intake, greater mobility and exercise, and establishing regular patterns of defecation after meals. Treatment of constipation is usually with both a stool softener (lactulose) and a stimulant (polyethylene glycol). Enema is contraindicated in neutropenic patients, due to the risk of intestinal perforation. Bowel obstruction may require a colostomy.

Neurogenic bowel is a distinct cause of constipation.

- In case of spinal cord lesion (spastic bowel, hypertonic anal sphincter and intact sacral reflexes) rectal suppositories help for sphincter relaxation, in addition to fluid/fiber intake. Laxatives causing excessive softening should be avoided.
- Neurogenic bowel due to a sacral nerve root lesion shows reduced peristalsis, flaccid sphincter and absent sacral reflexes. Management includes straining, abdominal massage, laxatives, suppositories and increased fluid and fiber intake.

Diarrhea

Try and identify treatable causes of diarrhea e.g. enteral infection (bacterial, viral, parasitic), non-enteral infection (otitis media, pneumonitis, urinary tract infection), malabsorption, constipation with overflow or drug-induced diarrhea (antibiotics, excessive laxative use, chemotherapy-induced mucositis). Counselling about contaminated food, poor hand-washing technique and the use of contaminated toys needs to be reinforced. Management of diarrhea includes hydration, correction of electrolyte and acid-base imbalance, dietary modifications. Antibiotics are usually not required except in case of documented bacterial or parasitic infection.

Dyspnea

Breathlessness is a frequent symptom in the palliative care of children with cancer and AIDS. It may be:

- Related to the underlying disease: effusion, consolidation, ascites, Kaposi's sarcoma, lymphangitis, lymphoid interstitial pneumonitis.
- Related to treatment, e.g. post-radiation fibrosis.
- Infective: bacterial pneumonia, pneumocystis carinii pneumonitis (PCP), CMV pneumonitis, tuberculosis
- Others: anemia, encephalopathy asthma, cardiac failure.

Nonpharmaceutical Measures

Dyspnea generates anxiety, which in its turn exacerbates dyspnea in a vicious cycle fashion. Thus non-pharmacological measures aiming at reducing anxiety are very important: sitting the child up, with appropriate ventilation, reassuring words relaxation and distraction techniques.

Pharmaceutical Measures

Severe dyspnea requires adequate sedation with morphine and/or benzodiazepine (e.g. oral, rectal or parenteral diazepam). Morphine dose is to be increase by one-third in children who are already receiving morphine.

Specific symptoms will require different management:

- *Acute stridor*: Try and clear airway, oxygen administration, adrenaline nebulization, high dose IV dexamethasone. Tracheostomy may be considered in a hospital setting if the overall prognosis allows it.

- Pneumothorax is treated symptomatically, unless drain is required.
- *Pleural effusion:* Pleural drainage brings immediate relief, but malignant effusions will recur soon after pleural tab, unless pleurodesis is done. Talc is the most effective sclerosing agent.¹⁸
- *Bronchospasm:* Oxygen, bronchodilator nebulization, steroids.
- *Cardiac failure:* Oxygen, diuretics, morphine.
- *Pneumonia in a child with AIDS:* Antibiotics; if PCP then give high-dose cotrimoxazole, steroids and high-dose oxygen; in case of lymphoid interstitial pneumonitis, give pulsed steroids, bronchodilators, physiotherapy, oxygen and ART.

Hiccup

Hiccup is a common cause of distress, causing interruption to normal activity, sleep and feeding disturbances.¹⁹ Possible mechanisms are phrenic nerve or diaphragmatic irritation (tumor or chest infection), vagus nerve irritation (gastro-oesophageal reflux, oesophagitis, hiatus hernia, ascites or liver tumor), metabolic imbalance (uremia, hyponatremia), brainstem tumor or drugs (benzodiazepines, corticosteroids and barbiturates).

Nonpharmaceutical Measures

- Pharynx stimulation (swallowing some food and drinking cold drinks)
- Vagal stimulation (breathing through a paper bag)
- Small frequent meals to reduce gastric distension.

Pharmaceutical Measures

- Prokinetics (domperidone or metoclopramide)
- Antacids and antiflatulents
- Smooth muscle relaxation (nifedipine or baclofen)
- Central suppression (chlorpromazine, promazine or haloperidol)

Psychological Distress

Psychological counselling is very important for compliance. Children react to the distress and emotions of adults. The family has different phases of reactions, from denial, anger, grief that may require time to reach acceptance of the situation. When the child is told about the disease and is allowed to talk about it, they will understand their distress and be in a better emotional state. On the contrary, when relatives don't want the child to be told, it leads to isolation, depression, anger and abnormal reactions.

Anxiety

Symptoms of anxiety include subjective feeling of apprehension, feeling tense, worried or restless, irregular or fast heartbeats, chest pain, rapid, difficult breathing,

or sweating, feeling of suffocation, difficulty in concentrating. Anxiety in parents and in the child needs to be addressed by empathetic listening, psychotherapy, relaxation therapy (music, etc.). A mild anxiolytic may be indicated in moderate to severe anxiety.

Depression

Chronic and terminally ill children are at risk of depression. Manifestations of depression in children range from sadness to suicidal ideation. Change in appetite or weight, sleep disturbance, fatigue and loss of energy, diminished ability to think or concentrate, lack of reactivity, feelings of hopelessness and worthless. One should assess situational factors and previous psychiatric history or treatment. The mainstay of depression management is psychological counselling. This interaction itself may be therapeutic. Promoting the child's autonomy, drawing on their strength rather than focusing on growing limitations and dependency; discussing short-term goals is a positive concrete step. Cognitive behavioral therapy, i.e. talking with patients about their feelings and reframing their ideas, is a helpful approach. Pharmaceutical measures are only required if counselling is not entirely effective: tricyclic antidepressants, benzodiazepines and stimulants may be used.

Weakness and Fatigue

Weakness and fatigue are commonly encountered symptoms among children on palliative care. Energy depletion makes the child sleep during the day instead of the night, leading to insomnia. Such sleep cycle disturbance should be addressed by having a timetable for meals, activities, sleep and dealing with the child as with the other siblings. The importance of play needs to be emphasized, since it enables the child to relax and to lead a near-to normal life. Readjustment to school in this phase of the disease would lead to excessive stress. However, home schooling is to be encouraged, preferably by a third person. Bringing a non-relative into the child's life can give a break to the family.

Insomnia

When insomnia is related to uncontrolled pain, adequate pain relief is the mainstay. Insomnia is often a manifestation of anxiety and depression, which need proper pharmacological and psychological management, with particular emphasis on listening to the child's fears and feelings. Children who picture death as a deep sleep may fear sleep when they reach the terminal phase of their disease. Simple nonpharmacological measures include providing the child with a comfortable mattress and posture, avoiding coffee, tea and alcohol before bedtime, avoiding loud noises near the room. Drinking warm milk at bedtime may be beneficial.

Skin Conditions

Pruritus is a common side effect of morphine, which may be replaced by another opioid. Other causes of pruritus include dry skin, atopic dermatitis, contact dermatitis, chicken pox, scabies (disseminated scabies in HIV positive children) and obstructive jaundice. Simple skin care consists of avoiding overheating, sweating and prolonged hot baths, washing no more than once daily and frequent application of skin moisturizer or oily calamine lotion. Scratching should be discouraged, finger nails kept short and smooth. Slightly sedating systemic anti-histaminics may help.

In children with AIDS, the management of seborrheic dermatitis, psoriasis, bacterial and fungal infection, Herpes zoster, etc. requires specific local and systemic treatment. It may include palliative radiotherapy in condylomata accuminata and kaposi sarcoma (particularly if fungating tumor).

ALTERNATIVE MEDICINE

Most patients in terminal part of disease go for alternative medicine. Alternative treatment options, such as ayurvedic medicine, homeopathy, etc. should not be disregarded for symptom relief. Patients should be allowed to continue allopathy in parallel with any other alternative therapy opted for. Acupressure and acupuncture are particularly effective for nausea, vomiting and pain relief.

PALLIATIVE RADIATION THERAPY

Radiation therapy is an important nonpharmacologic modality in the palliative care management of incurable, loco-regionally advanced and metastatic childhood cancers.²⁰ An average 40 to 60 percent symptom response can be achieved with palliative radiation therapy in children. The radiation dose needed to achieve palliation is much lower than therapeutic radiotherapy, with no or minimal radiation-induced morbidity.^{21,22} Three-dimensional conformal radiotherapy (3D CRT), intensity-modulated radiotherapy (IMRT) and image-guided radiotherapy (IGRT) allow treatment of the loco-regional tumor site without damaging normal tissues and organs. Conditions amenable to radiotherapy are:

- Bone metastases or spinal cord compression causing pain and immobility: a single fraction of 5 to 8 Gy may be sufficient for symptom relief; or 15 to 30 Gy in 5 to 15 fractions.
- Brain tumor or metastases causing headache, vomiting and neurological deficit: 18 to 30 Gy are administered in 10 to 15 sittings.
- Advanced Wilms' tumor, neuroblastoma, rhabdomyosarcoma may manifest as respiratory distress, dysphagia, intestinal or urinary obstruction: 12 to 30 Gy in 10 to 15 fractions.

- Solid tumors or metastatic hematologic malignancies causing compression, bleeding or fungation required 10 to 30 Gy in 2 to 10 fractions.

Adjuvant antiemetic, steroid, diuretic, laxative and antispasmodic drugs may be required by radiation-induced cellular and vascular edema.

HOME-BASED PALLIATIVE CARE

Palliative care at home enables to take care of the child in a friendly and familiar environment. It is provided by a complete home-care team (physician, nurse and counsellor) able to provide physical, psychological, social and spiritual care as well as advising, training and supporting the family. Home care visits are to be made at least weekly, in plain clothes and not in hospital vehicle so as to avoid social stigma, which may be a concern for the family. Siblings should contribute to the care of the sick child, which will not traumatize them but help them cope better with their sibling's departure.

END OF LIFE CARE

Even though the family may be well aware of the life-threatening illness and may understand that there is progression of the disease or relapse, the death of a child is particularly traumatic. Emotional expression enables to avoid dysfunctional reactions. Communication may be compromised by the anxiety and dread many physicians face when discussing impending death.^{23,24}

Communication

Good doctor patient communication is essential at this time. Terminally ill patients experience less stress and unwanted aggressive medical care if they have end-of-life discussions with their healthcare team. Aggressive care is associated with worse patient quality of life and worse bereavement adjustment.²⁵ Discussing what choices the family has at this time allows them some autonomy and control during this process. Many families will now have fewer resources to cope, e.g. financial, emotional and other support systems. A detailed discussion of beliefs and any necessary rituals at the time of death may be needed in case the treating team is unfamiliar with them.

When a child is dying, the child should have discussions with the doctors and treating team to answer their fears and questions in an age-appropriate manner. Many children will have heard of the death of fellow patients, they understand that things are not going well by their own health or the response of grief stricken parents. An unmet need of pediatric cancer patients includes a paucity of information and discussion about death.⁵ Honesty, compassion and reassurance of making things as pain free as possible are of assistance. The team can facilitate communication between the family members, this is important

in the case of teenage children, where their autonomy and wishes need to be expressed. This may stimulate sharing of emotions, facilitate in saying farewells and be a meaningful time for the family.

The grieving process as outlined by Kübler-Ross starts again at this time, i.e. denial, anger, bargaining, depression and acceptance.²⁶ The way in which families grieve depends on the personality of the individual, relationship, circumstances and experience of cancer, cultural and religious beliefs, coping skills, past experiences, support systems, and even socioeconomic status.²⁷ Siblings of cancer patients are an important group who should receive bereavement counselling along with the parents and preferably separately as well.²⁸

Symptom Control

Most children in the terminal phase of cancer or AIDS develop devastating physical symptoms for weeks to months before death, e.g. pain, breathlessness, fever and bleeding. Patients with more severe symptoms usually present to a new tertiary care hospital or return to their treating centres. Medical challenges in treating symptoms towards the end of life include alteration of drug pharmacokinetics due to malnutrition, low albumin, impaired liver and kidney function. The child should be frequently assessed for relief of symptoms and development of side effects of multiple drugs and opioids.²⁹

It is often difficult for families to maintain adequate blood and blood component therapy. Judicious use of platelet transfusions and addition of medications like tranexemic acid and local measures may decrease hemorrhage. Occasional packed red cell transfusions as per the discretion of the physician may improve quality of life and activity in a dying child. Towards the end, family members should accept anorexia and aversion to food, not forcing food or fluids since this can lead to aspiration. Allowing gentle massage helps the family stay in touch and provide care. Supplemental nutrition may be beneficial in the treatment of advanced cancer, where the quality of life would otherwise suffer and death would be caused by malnutrition or dehydration rather than the underlying disease.³⁰

Supportive measures should be maintained till the end. But it is important for patients and families to understand that the decision to start or withhold resuscitation (interventions that provide cardiovascular, respiratory, and metabolic support to maintain and sustain the life) is theirs and should be taken before any acute event occurs. "Do not resuscitate" orders should be written and signed by the parents in advance.

Place of Care

The decision on where to care for a dying patient depends on choice, home situation, beliefs and finances. All the options should be discussed with the child, if old enough,

and family. The aim is to provide a secure and comforting environment and provide measures to provide comfort and relief at the end of life. Home care is an option for children where the family or additional staff can provide care at home. In larger cities of India, palliative home care teams are present which provide free home visits, symptom management, psychological support and bereavement counselling. Unfortunately, these are not yet available in rural areas. Hospice care services ensure good quality of life in a few institutions and clinics with good community networks in several states of India. Inpatient care may be an option for some families if the child needs round-the-clock care for symptom management or if hospice like care cannot be given at home.

Palliative Sedation

Palliative sedation has been an area of debate, even among palliative care providers, due to its double effect. Under the principle of double effect, the intended effect (relieving suffering) would be considered allowable as long as any risks or negative effects (i.e. shortened survival) are unintended by the health care professional. Palliative sedation is used to alleviate pain and symptoms, mainly delirium and dyspnea. Sedation in these circumstances is often on a temporary basis and reversible in about one fourth of patients.³¹

Recognizing when Death is Near

Patients may withdraw emotionally or sleep more, they may be confused and unable to recall recent events. The child's skin may become mottled, cold or pale. The heart rate may become irregular, urine output may decrease or even stop. Respiration may be labored or Cheyne-Stokes respiration – very shallow breaths and alternating periods of apnea and deep, rapid breathing, may occur. As the end draws the child may experience more symptoms such as restlessness, which is distressing to the family. Hence frequent communication is needed to provide updates on the condition of the child, as well as revision of treatment for new or exacerbating symptoms.

When death occurs, expressions of grief by those at the bedside vary greatly, and are dictated by culture and preparedness for death. The healthcare team needs to be empathetic and supportive of the family. They should help with hospital formalities and provide bereavement counselling. Care and understanding at this time assists the family in coping with grief and makes them feel that their child was loved and cared for in the best possible way.

Procedural Sedation and Analgesia in Pediatric Emergency Room

Suresh Gupta

INTRODUCTION

Pain and anxiety are common problems in pediatric emergencies. Most of the diagnostic and therapeutic procedures are associated with pain. Inadequate relief of pain associated with procedures may have acute and long-term consequences. By providing pain relief, the emergency provider will face a less anxious and more co-operative child, resulting in better outcome. Failure to co-operate during management is likely to result in a sub optimal outcome. But still, children continue to receive less pain medications as compared to adults.^{1,2}

Procedural sedation is a term that describes these interventions. Conscious sedation is another term that is sometimes used. However, because effective sedation often alters consciousness, this term is less accurate. Analgesia and/or sedation should be used any time a child complains or experiences pain and anxiety. Physicians caring for children are often faced with the difficult task of separating pain from anxiety and deciding which the predominant contributor to child's state is. But very often, anxiety amelioration is needed along with pain reduction. The clinical situation decides the method of pain management. No single drug or drug combinations in any fixed doses will be successful in every child for a given procedure. It is often necessary to titrate the medication doses according to desired level of analgesia and sedation. This article intends to review the current trends in the safe and effective methods for analgesia and sedation in children.

PHYSIOLOGY OF PAIN

International Association for the Study of Pain has defined the pain as "unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in such terms of damage". The physiologic basis of pain is now well understood.³

Tissue damage initiates the release of local mediators, such as bradykinin, substance P, prostaglandins, and potassium. These mediators heighten nociception and facilitate the communication of painful sensations to the spinal cord and the brain. Tissue injury also leads to release of histamine and serotonin, which results in increased pain sensitivity in areas surrounding the site of initial injury. Pain is multifactorial and subjective. There are several factors, which affect the nature of pain a child experiences. The developmental age, cognitive and emotional level, underlying medical condition, previous painful events, culture and environment of child greatly influence the pain process. Physician's attitude, experience and competence can greatly affect the pain management process.⁴ The response to pain differs with the level of development. Treatment strategies should account for these developmental changes.⁵

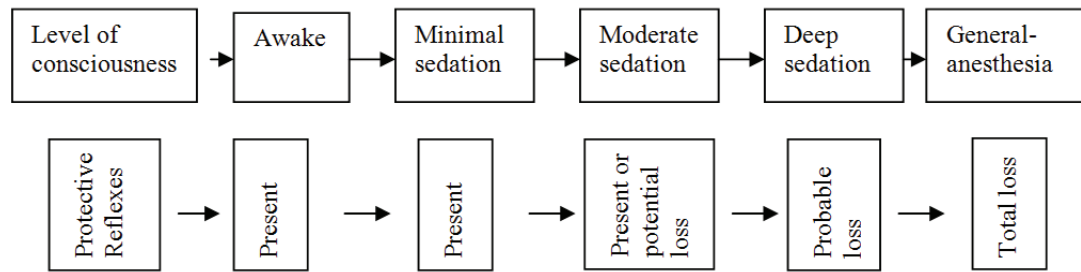

- *Less than six months:* Infants do not express anticipatory fear. Their level of anxiety reflects that of the parent.
- *6 to 18 months:* Infants begin to develop fear of painful experiences and withdraw when pain is anticipated.
- *18 to 24 months:* Children express pain with words, such as "hurt" or "boo boo."
- *Three years:* Children more reliably assess the pain they feel. They begin to localize pain and identify external causes. However, they depend upon a visual injury or cause for adequate localization and are unable to understand a reason for pain.
- *Five to seven years:* Children in this age group have improvements in understanding of pain, the ability to localize internal pain, and co-operation.

TERMINOLOGY

Procedural sedation and analgesia is a continuum which may progress from mild sedation to general anesthesia.⁶

Table 1: Levels of sedation and clinical response

	<i>Verbal response</i>	<i>Pain response</i>	<i>Airway response</i>	<i>Breathing</i>	<i>Circulation</i>
Anesthesia overdose	0	0	0	0	0/+
Anesthesia	0	0	0	0/+	++
Deep sedation	0	+	+	++	+++
Moderate sedation	+	++	+++	++++	+++++
Minimal sedation	+++	++++	++++	+++++	+++++
No sedation	+++++	+++++	+++++	+++++	+++++

**Fig. 1:** Continuum of depths of sedation

Following are the commonly used terms to define the level of sedation and analgesia (Table 1 and Fig. 1).

- *Analgesia:* Relief of pain without intentionally producing a sedated state. Altered mental status may be a secondary effect of medications administered for analgesia.
- *Minimal sedation:* The patient responds normally to verbal commands. Cognitive function and co-ordination may be impaired, but ventilatory and cardiovascular function is unaffected.
- *Moderate sedation/analgesia:* The patient responds purposefully to verbal commands either alone or accompanied by light touch. Patient is able to maintain airway and adequate ventilation without intervention. Cardiovascular function is also maintained.
- *Deep sedation/analgesia:* The patient cannot be easily aroused but responds purposefully to noxious stimulation. Patient may require assistance to maintain airway and adequate ventilation. Cardiovascular function is usually maintained.
- *General anesthesia:* The patient cannot be aroused. Often requires assistance to maintain airway and positive pressure ventilation. Cardiovascular function may be impaired.
- *Dissociative sedation:* Dissociative sedation is a trance-like cataleptic state in which the patient experiences profound analgesia and amnesia, but retains airway protective reflexes, spontaneous respirations, and cardiopulmonary stability. Ketamine is the pharmacologic agent used for procedural sedation that produces this state.

While providing pain and anxiety relief is important, the safety of the child during procedural sedation should never be compromised.⁵ The clinician must determine the appropriate level of sedation and/or analgesia required for a particular procedure. In addition to medications, verbal reassurance, distraction techniques, and hypnosis may be helpful. The purpose of sedation and analgesia for painful procedures are to:

- Maintain patient safety and welfare
- Minimize physical pain and discomfort
- Control anxiety, minimize psychological trauma, and maximize amnesia
- Control behavior to allow safe performance of procedures
- Ensure safe discharge.

INDICATIONS FOR SEDATION

Sedation should be considered for any procedure, which provokes distress in a child. The route of administration may include intravenous (IV), intramuscular (IM), transmucosal (intranasal, sublingual), per rectal (PR), per oral (PO), or inhalational. It is easy to titrate the dose with intravenous route but with intramuscular route the dose cannot be titrated. With oral, rectal and intranasal agents, the onset, depth and duration are less predictable than parenterally administered drugs. It is better to start with the lowest recommended dose and then incremental doses can be given at 2 to 5 minutes intervals till the desired level of sedation is obtained. Each institution should have its own guidelines for assessment and monitoring of

pediatric patients during and after sedation. The pediatric procedural sedation and analgesia can be divided into three phases (i) Preprocedure phase, (ii) Intraprocedure phase and (iii) Postprocedure phase.

Preprocedure Phase

Assessment

Patients should be evaluated prior to the procedure for their suitability for sedation.⁵ Before sedating any child a complete history and physical examination should be done and the American Society of Anesthesiologists (ASA) class is assigned to the patient (Table 2). AMPLE is good mnemonic for assessment purpose for pediatric sedation.

- Allergies
- Medications
- Past medical history
- Last meal (time of solids and liquids taken)
- Events leading to need for sedation.

American Society for Anesthesiologists (ASA) has assigned categories to the patient for sedation purposes. Suitability for sedation ranges from excellent to extremely poor for patients in class I through class V. Children with ASA classes I and II are generally reasonable candidates for mild, moderate, and deep sedation outside of the operating room. For those with ASA classes III and IV, special needs, or airway abnormalities, consultation with an anesthesiologist or subspecialist is recommended. The balance of risks and benefits must be weighed for each individual.

Equipment

To handle any emergency arising during the procedure, following monitoring and resuscitation equipment should be ready at the bedside:

- Oxygen source
- Intubation tray
- Oral airway
- A source of suction
- Cardiorespiratory monitor
- Resuscitation medications (Injection epinephrine, atropine, hydrocortisone)
- Pharmacological reversal agents like naloxone and flumazenil.

Personnel

The minimum personnel during sedation should include a physician and a nursing staff trained in pediatric advanced life support (PALS).⁷ The person should be well versed with the drugs, which are going to be used on that patient. It is important that the person responsible for sedation and monitoring is not doing the procedure. Any time the patient gets unstable, the procedure should be withheld and stabilization should be done first.

Fasting Guidelines

Before providing sedation, the fasting for adequate period should be ensured to prevent pulmonary aspirations.^{7,8} It's always better to plan and conduct procedure

Table 2: American Society of Anesthesiologists (ASA) classification

ASA class	Description	Examples
1	A normal, healthy patient, without organic, physiologic, or psychiatric disturbance	Healthy with good exercise tolerance
2	A patient with controlled medical conditions without significant systemic effects	Controlled hypertension, controlled diabetes mellitus without system effects, cigarette smoking without evidence of chronic obstructive pulmonary disease (COPD), anemia, mild obesity, age less than 1 or greater than 70 years, pregnancy
3	A patient having medical conditions with significant effects intermittently associated with significant functional compromise	Controlled congestive heart failure (CHF), stable angina, old myocardial infarction (MI), poorly controlled hypertension, morbid obesity, bronchospastic disease with intermittent symptoms, chronic renal failure
4	A patient with a medical condition that is poorly controlled, associated with significant associated with significant dysfunction and is a potential threat of life	Unstable angina, symptomatic COPD, symptomatic CHF, hepatorenal failure
5	A patient with a critical medical condition that is associated with little chance of survival with or without the surgical procedure	Multiorgan failure, sepsis syndrome with hemodynamic instability, hypothermia, poorly controlled coagulopathy
6	A patient who is brain dead and undergoing anesthesia care for purposes of organ donation	
E	This modifier is added to any of the above classes to signify a procedure	

Table 3: ASA fasting guidelines for procedural sedation

<i>Ingested material</i>	<i>Minimum fasting period</i>
Clear liquids	2 hours
Breast milk	4 hours
Infant formula	6 hours
Non-human milk	6 hours
Light meal	6 hours

on elective basis. The recommendations given by ASA, for fasting during an elective situation are given in Table 3. Fasting periods apply to healthy patients of all ages who are undergoing elective procedure. Those with gastroesophageal reflux (GER), obesity, may require appropriate pharmacological intervention. In emergency settings patients are rarely fasting. Therefore if possible, it is always better to delay the procedure. Should the procedure be conducted, lightest possible sedation should be given.

Important factors that may increase the risk for aspiration include possibility of a difficult airway, conditions predisposing to esophageal reflux (i.e. elevated intracranial pressure, gastritis, bowel obstruction, or ileus), Extremes of age (e.g. <6 months or >70 years), severe systemic disease with functional limitation (ASA class ≥ 3) and altered mental status. Fasting is not needed for minimal sedation, sedation with nitrous oxide (in oxygen) alone and moderate sedation where the child maintains verbal contact.

Checklist

The team providing sedation ensures following before doing the procedure under sedation. A checklist will reduce the possibility of missing or omitting an important component.

- Patient's medical history has been obtained
- Pre-procedure laboratory testing (at the discretion of Physician)
- Informed consent
- Functioning I/V line
- Patient clinical condition should be appropriate for sedation
- Child and parents must be explained the procedure, and about the sedation
- There should be written order for sedation by the consultant in the case sheet
- An accurate weight is documented
- Vitals signs are recorded and trends should be followed closely any change in the base line vitals should be addressed immediately
- Airway assessment in non-intubated patients
- General neurological status.

Monitoring

It is an important component of pediatric procedural sedation and analgesia. A proper monitoring will not only

ensure patient safety but will also help in providing effective sedation and avoid sedation disasters.⁹ Monitoring includes visual observation, determination of vital signs, and pulse oximetry. The face and mouth and movement of the chest wall should be observed continuously. Heart rate and oxygen saturation (pulse oximeter) should be monitored and recorded continuously. Vital signs are recorded at the beginning of the procedure, after administration of the drug, when the procedure is completed, during early recovery, and when recovery is completed. Patients undergoing deep sedation or patients with underlying illness should have vital signs measured at least every five minutes. End-tidal CO₂ (ETCO₂) monitoring is increasingly available in critical care settings for nonintubated patients and is useful to assess ventilation during sedation and analgesia.¹⁰ The ETCO₂ is more sensitive for detecting hypoventilation than clinical assessment. Increases in ETCO₂ will detect respiratory depression before hypoxemia occurs, particularly in those who are receiving supplemental oxygen.

Complications are most likely to occur within 5 to 10 minutes of intravenous drug administration and immediately postprocedure when stimuli associated with the procedure have gone. So monitoring becomes more significant during these periods.

Intraprocedure Phase

Whenever drugs for sedation are considered for a procedure, safety and welfare of the patient is always a priority. The goal of sedation is to minimize pain, discomfort, and anxiety and maximize the co-operation. Sedation is a continuum. A child can easily slip from minimal or moderate sedation into deep sedation where the chances of losing airway protective reflexes become high. In addition to this child may also develop cardiorespiratory depression. It highly suggested the physicians interested in providing sedation to children should be trained in pediatric advanced life support and sedation techniques.

The drugs to be used during sedation should have been thought well in advance depending on the age, condition and type of procedure being conducted. For painless procedures like CT scan or MRI, only sedation without analgesia is required. Midazolam or propofol are good agents to provide sedation under these circumstances. On

Table 4: Ramsay score for level of sedation

<i>Ramsay scale</i>	<i>Level of sedation</i>
I	Anxious, agitated or restless
II	Cooperative, oriented and tranquil
III	Responds to verbal command
IV	Responds to gentle shakily
V	Responds to noxious stimuli
VI	No response to noxious stimuli

the other hand, the painful procedures like bone marrow aspiration or kidney biopsy, one needs deep sedation with analgesia. A trained person should continuously monitor the patient vitals and act immediately any time complication occurs. Consultant should prescribe the drug and dosage. Adequate sedation should be obtained before starting the procedure. Never cover face during procedure; it hinders the physician watching the patient. Monitor vital signs pulse, blood pressure (BP), respiratory rate (RR), Saturation, level of consciousness (Ramsay Score-Table 4) every 15 minutes during conscious sedation, every 5 min during deep sedation in all the hemodynamically unstable patients irrespective of degree of sedation.^{9,11}

During the procedure, any question concerning the adequacy of patient airway, ventilation or hemodynamic status should be addressed immediately and all other things are only second priority.

Postprocedure Phase

To facilitate smooth recovery from the effect of sedation following steps are very useful:

- Should be quiet with dim lights
- All the equipment needed to deal with any emergency arising, should be available
- A physician who is adept at airway management should be immediately available
- NPO status must be maintained till the patient is fully awake oriented and the vital signs have returned to the baseline
- Drapes should be placed in such a way that airway and chest motions can be visualized all the time.

Vital signs (pulse rate and volume, SpO₂, BP) should be monitored every 15 minutes during minimal sedation

and every 5 minutes during deep sedation for at least 60 minutes and the patient should not be left alone. Monitoring should continue until the child meets criteria for safe discharge. The post sedation "Aldrete Score" should be 8-10 before the patient is discharged from the procedure area (Table 5).¹² The important components of discharge criteria are:⁷

- Airway patency and stable cardiovascular function
- Easy arousability with intact protective reflexes
- Ability to talk (if age-appropriate)
- Ability to sit up unaided (if age-appropriate)
- Adequate hydration with management of any nausea or vomiting
- Appropriate management of any continued pain
- Young infants or children who are handicapped should return to the level of responsiveness observed before sedation.

NONPHARMACOLOGICAL APPROACHES

Both nonpharmacologic and pharmacologic interventions are used to manage acute pain.

Nonpharmacological methods for reducing distress in the child are as important as using the sedatives and analgesics. The use of these methods reduces need and doses of the sedation drugs. Every emergency room should have people who are trained in these nonpharmacological methods.

Psychological Preparation and Relaxation

Psychological preparation of the child and parents may dramatically reduce distress. These should be age specific and may include careful explanation, distraction, hypnosis and reassurance. The environment should be as relaxing as possible.¹³

Parental Presence

The decision of parental presence in the procedure room depends on the age of the child, needs of the child and the ability of the parents to remain calm.¹⁴ School going and young children may feel more relaxed if their parents are on their side during painful procedures. Informed parents rarely interfere with the procedure. But, a parent who moans and groans during the procedure will disrupt any chances of relaxation. For such parents, it may be better that they wait outside the treatment area.

Behavior Therapy

Children should always be encouraged to express their feelings and emotions.¹⁵ It is always better not to lie or downplay a child's perception of pain. Consistent positive enforcement and emphatic tone of physician can make the child more comfortable.

Table 5: Aldrete score for discharge following procedural sedation

Activity	Able to move 4 extremities	2
	Able to move 2 extremities	1
	Able to move 1 extremities	0
Respiration	Able to deep breath/cough freely	2
	Dyspnea/limited breathing	1
	Apnea	0
Circulation	BP + 20% of basal BP	2
	BP + 20-50% of basal BP	1
	BP + 50% of basal BP	0
Consciousness	Fully awake	2
	Arousable on calling	1
	Not responding	0
Color	Pink	2
	Pale, dusky, blotchy	1
	Cyanotic	0

Total Aldrete Score

Hypnosis

Hypnosis can be very useful in those children who are hypersuggestible. Guided imagery is used to facilitate pain control during procedure. The type of hypnotic approach depends on the developmental age of the child. It is most effective when used in a quiet and comfortable environment. However, most emergency physicians prefer nonhypnotic pain coping strategies because hypnosis is difficult to provide in busy emergency department.¹⁵

Restraint

In spite of best efforts of physician to relax the child, some kind of restraint is often needed to conduct the procedure. It is always preferable to provide a short period of effective restraint on a papoose board rather than an extended period of struggling with an uncooperative and immobilized child.¹⁶ But using a restraint does not mean that other techniques of pain control are not required. Psychological and pharmacological techniques should be used in conjunction with restraint. Though immobilization decreases struggling by negative feedback, inadequate restraint may encourage struggling by positive feedback.

PHARMACOLOGICAL APPROACHES FOR SEDATION

The American College of Emergency Physicians has developed a clinical policy describing an evidence-based approach to the pharmacologic agents used for sedation and analgesia of children in the emergency department. A wide range of short-acting sedative-hypnotic and analgesic medications are available.¹⁷⁻¹⁹ Many of these agents have multiple routes of administration. The choice of drug is based upon the type of procedure and the patient's underlying medical condition. Procedures that are not painful but require the child to remain still can generally be performed with sedation alone. Children undergoing painful procedures typically require analgesia as well as sedation. Table 6 provides the list of pharmacological interventions used for pediatric procedural sedation and analgesia. The commonly used sedation protocols are: (i) Ketamine dissociative sedation, (ii) Fentanyl-midazolam sedation, (iii) Propofol sedation and (iv) Nitrous oxide sedation (Figs 2 to 4). Table 7 provides the suggested methods for sedation-analgesia for procedures in pediatric emergency room.

Table 6: Suggested methods for sedation-analgesia for procedures in pediatric emergency room*

<i>Procedure</i>	<i>Local anesthetics</i>	<i>Sedation</i>
IV Catheter placement	Buffered lidocaine, SC or Saline with benzyl alcohol, SC or EMLA and sometime	Nitrous oxide for significant or Midazolam, PO (anxiolysis)
Lumbar puncture	Buffered lidocaine EMLA	Nitrous oxide or Midazolam (PO/IN/PR) or Fentanyl/midazolam, IN or Ketamine, PO/IV/IM
Intensely painful procedures	Buffered lidocaine	Ketamine-midazolam, IV/IM or Fentanyl midazolam, IV
CT Scan/MRI		Midazolam (PO/IN/IM/PR) or Pentobarbitone (IM/IV) or Propofol (IV)

*Parental presence, comforting, and distraction should be encouraged during all procedures

EMLA = Eutectic mixture of local anesthetics, SC = Subcutaneous, PO = Per oral, IN = Intranasal, PR = Per rectal, IV = intravenous, IM = Intramuscular

Definition of dissociative sedation

A trance like cataleptic state induced by the dissociative agent ketamine, characterized by profound analgesia and amnesia, with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.

Characteristics of the ketamine "Dissociative State"

- *Dissociation:* After administration of ketamine, the patient passes into a fugue state or trance. The eyes may remain open, but the patient does not respond.
- *Catalepsy:* Normal or slightly enhanced muscle tone is maintained. On occasion, the patient may move or be moved into a position that is self-maintaining. Occasional muscular clonus may be observed.
- *Analgesia:* Analgesia is typically substantial or complete.
- *Amnesia:* Total amnesia is typical.
- *Nystagmus:* Nystagmus is typical.
- *Maintenance of airway reflexes and cardiovascular stability.*

Contd...

Indications		
Short, painful procedures, especially those requiring immobilization (e.g. facial laceration, burn debridement, fracture reduction, abscess incision and drainage, central line placement, tube thoracostomy).		
Contraindications: Absolute (Risks essentially always outweigh benefits)		
<ul style="list-style-type: none"> Age younger than 3 months (higher risk of airway complications) Known or suspected schizophrenia, even if currently stable or controlled with medications (can exacerbate condition) 		
Contraindications: Relative (Risks may outweigh benefits)		
<ul style="list-style-type: none"> Major procedures stimulating the posterior pharynx (e.g., endoscopy) increase the risk of laryngospasm, whereas typical minor ED oropharyngeal procedures do not. History of airway instability, tracheal surgery, or tracheal stenosis Active pulmonary infection or disease, including upper respiratory infection or asthma (higher risk of laryngospasm) Known or suspected cardiovascular disease, including angina, heart failure, or hypertension Avoid ketamine in patients who are already hypertensive Central nervous system masses, abnormalities, or hydrocephalus (increased intracranial pressure with ketamine) Glaucoma or acute globe injury, porphyria, thyroid disorder, or thyroid medication 		
Ketamine Administration: General		
<ul style="list-style-type: none"> Frame the dissociative encounter as a positive experience. Encouraging children to “plan” specific, pleasant dream topics in advance of sedation (believed to decrease unpleasant recovery reactions). Ketamine is administered when the physician is ready to begin the procedure. Ketamine is initially administered as a single IV loading dose or IM injection. IV Ketamine: IV route is preferable because recovery is faster and there is less emesis. Administer a loading dose of 1.5 to 2.0 mg/kg IV in children over 30–60 seconds. Additional incremental doses of ketamine may be administered (0.5 to 1.0 mg/kg) if initial sedation is inadequate or to accomplish a longer procedure. IM Ketamine: The IM route is especially useful if IV access cannot be consistently obtained. IV access is unnecessary for children receiving IM ketamine. Administer ketamine 4 to 5 mg/kg IM in children and repeat ketamine dose (full or half dose IM) if sedation is inadequate after 5 to 10 minutes (unusual) or if additional doses are required. 		
Route of administration	IV	IM
<i>Advantages</i>	<i>Ease of repeated dosing; less vomiting, slightly faster recovery</i>	<i>No IV access necessary</i>
Peak concentrations and clinical onset	1 minute	5 minute
Typical duration of effective dissociation	5–10 minute	20–30 minute
Typical time from dose to discharge	50–110 minute	60–140 minute
Coadministered medications		
<ul style="list-style-type: none"> Prophylactic anticholinergics are no longer recommended. Prophylactic benzodiazepines are no longer recommended for children; however, they should be available to treat rare, unpleasant recovery reactions, should they occur. Prophylactic ondansetron can slightly reduce the rate of vomiting (number needed to benefit 9 or more). 		
Procedure		
Adjunctive physical immobilization may be occasionally needed to control random motion. Adjunctive local anesthetic is usually unnecessary when a dissociative dose is used. Occasional repositioning of the head or suctioning of the anterior pharynx may be indicated for optimal airway patency.		
Potential adverse effects		
<ul style="list-style-type: none"> Airway misalignment requiring repositioning of head (occasional) Transient laryngospasm (0.3%) Transient apnea or respiratory depression (0.8%) Hypersalivation (rare) Emesis, usually well into recovery (8.4%) Recovery agitation (mild in 6.3%, clinically important in 1.4%) Muscular hypertonicity and random, purposeless movements (common) Clonus, hiccapping, or short-lived nonallergic rash of face and neck 		

Fig. 2: Ketamine dissociative sedation

Indications
<ul style="list-style-type: none"> Brief, painful procedures for which deep sedation is indicated, including fracture and dislocation reductions, incision and drainage of abscesses, cardioversion, tube thoracostomy, and central line placement.
Contraindications
<ul style="list-style-type: none"> Absolute (Risks essentially outweigh benefits): Known or suspected allergy to soy or eggs. Higher relative risk patients: Patients >55 years of age, debilitated, or with significant underlying illness (i.e. ASA physical status score 3 or 4)

Contd...

Contd...

Propofol Administration: General
<ul style="list-style-type: none"> Propofol induces sedation approximately 30 seconds after bolus injection, with typical resolution of clinical effects within 6 minutes. The most common ED dosing is with an initial bolus dose of 1 mg/kg followed by 0.5 mg/kg every 2–3 minutes as needed to achieve or maintain the desired level of sedation. This dosing applies to both adults and children. Propofol is typically titrated to slurring of speech and/or lid ptosis depending on the depth of sedation and degree of relaxation needed for the procedure.
Potential adverse effects
<ul style="list-style-type: none"> Respiratory depression or apnea leading to assisted ventilation (0%–3.9%). Transient hypotension (2.2–6.5%). Emesis (0–0.5%). Pain with injection (2–20%).

Fig. 3: Deep sedation with propofol

Caveats
<ul style="list-style-type: none"> Individual response to the drugs is variable and dependent upon the patient's underlying physiologic state and the presence of concomitant drugs/ medication. Maximum drug effect occurs 2–3 minutes after administration. Proceed slowly and patiently, allowing the medication to take full effect before giving the next dose. Have naloxone and flumazenil immediately available for over sedation and/or respiratory depression
Contraindications
<ul style="list-style-type: none"> Absolute (Risks essentially always outweigh benefits): Active hemodynamic instability or active respiratory distress or hypoxemia. Relative (Risks may outweigh benefits): Respiratory depression or altered level of consciousness or anticipated difficulty if ventilatory assistance should become necessary (e.g. facial deformity or trauma, small mandible, large tongue, trismus).
Procedure
<ul style="list-style-type: none"> Establish IV access Midazolam dose: IV (0.5–5 yr): Initial 0.05– 0.1 mg/kg, then titrated to max 0.6 mg/kg. IV (6–12 yr): Initial 0.025– 0.05 mg/kg, then titrated to max 0.4 mg/kg. Fentanyl Dose IV: 1 µg/kg/dose, may repeat q3min, titrate to effect The order of the drugs is one of personal preference. The ratio of analgesia to sedation is determined by the nature of the procedure. Some procedures require primary analgesia and secondary anxiolysis/ sedation (e.g. abscess incision and drainage, bone marrow aspiration, arthrocentesis, burn debridement, central catheter placement). In this case, administer fentanyl first. Others require primary anxiolysis/ sedation with secondary analgesia (e.g. lumbar puncture, simple foreign body removal); administer midazolam first. Administer local anesthesia if indicated after procedural sedation is initiated (this often serves to help gauge effectiveness of systemic analgesia). Perform the procedure. Additional doses of fentanyl or midazolam may be required if further pain or anxiety are noted based on the response and length of the procedure. If hypoxemia, over sedation, or slowed respirations are seen during or after the procedure, the patient should be first stimulated while oxygen is applied and the airway repositioned. If the patient's response is insufficient, assist ventilations with a bag-valve-mask. Reversal agents should be considered if there is not a prompt response to assisted ventilation.

Fig. 4: Moderate to deep sedation with intravenous midazolam and fentanyl

ADVERSE SEDATION EVENTS

Adverse events occur with all routes of administration and classes of medication, including those considered to have minimal effect on breathing. Poor outcomes also have been associated with excessive doses, drug interactions, administration by personnel without medical training, and, after discharge, drugs with long half-lives. The consequences of an adverse event that is not immediately recognized and treated can be devastating. In one retrospective report describing adverse sedation events in children, permanent neurologic injury or death was associated with adverse events that occurred in nonhospital-based facilities and with those for which resuscitative efforts were

inadequate.²⁰ Other factors that contributed to adverse events were:

- Inadequate and inconsistent physiologic monitoring
- Inadequate medical evaluation before sedation
- No independent observer
- Medication errors
- Inadequate recovery procedures.

Adverse events associated with procedural sedation for children are unlikely when standardized safe practices are observed. It has been suggested that implementation of hospital-wide guidelines for procedural sedation and analgesia may decrease the incidence of adverse events. This was demonstrated in a report describing 30,037

Table 7: Pharmacological agents used for procedural sedation and analgesia in children

Agent	Dose	Onset of Action	Duration of action	Remarks
Benzodiazepines				
Midazolam	IV: 0.05 mg/kg, maximum single dose 5 mg; may be repeated up to maximum total dose of 0.4 mg/kg	1-2 min	30-60 min	Sedative and hypnotic agents with potent amnestic effects. May suppress ventilation when used in combination. Occasionally cause a paradoxical excitatory reaction. For hemodynamically unstable patients, decrease dose by 50%.
	IM: 0.1-0.2 mg/kg	5-15 min	30-60 min	
	IN: 0.2-0.4 mg/kg			
	PR: 0.5-1 mg/kg	5-10 min	30-60 min	
	PO: 0.25-0.5 mg/kg; maximum total dose 20 mg	10 min	1-2 hours	
Lorazepam	IM, IV: 0.05-0.1 mg/kg maximum single dose 4 mg	IV: 3-5 mins	2-6 hours	
	PO: 0.05-0.1 mg/kg maximum single dose 2 mg	IM: 10-20 mins	2-6 hours	
		PO: 60 mins	2-8 hours	
Diazepam	IV: 0.1-0.2 mg/kg	2-3 mins	30-90 mts	
	PR: 0.3-0.5 mg/kg	5-15 mts	2-4 hours	
Barbiturates				
Pentobarbital	IV: 1-3 mg/kg, may be repeated up to 6 mg/kg	1-5 mins	15-60 min	Short acting sedative-hypnotic agents. None has analgesic properties. Typically the sedative of choice for patients with head-trauma, status epilepticus or suspected increased intracranial pressure. Side effects include dose-dependent myocardial depression and hypotension. Other adverse effects include bronchospasm, laryngospasm, cough and anaphylaxis.
	IM: 2-5 mg/kg	5-15 min	2-4 hours	
	PO: 2-3 mg/kg	15-60 min	2-4 hours	
Thiopental	PR: 25 mg/kg	5-15 min	60-90 min	
Methohexital	PR: 20-30 mg/kg	5-15 min	30-90 min	
Narcotics				
Morphine	IV: 0.05-0.1 mg/kg	5-10 min	2-4 hours	Remain the gold standard for treatment of severe pain. Codeine is less potent and efficacious than morphine. Fentanyl, a synthetic narcotic, is 50-100 times more potent than morphine. An unusual complication associated with its use is chest-wall rigidity (with larger doses, given rapidly usually >5 mcg/kg, especially in infants.) The most common adverse effects of narcotics are hypoventilation, apnea and hypotension.
Fentanyl	IV: 1-4 mcg/kg	2-3 mins	20-60 min	
Codeine	0.5-1.0 mg/kg	15-60 min	4-6 hours	
Other agents				
Ketamine	IV: 0.5-2 mg/kg	1-2 mins	15-60 min	Ketamine produces potent analgesia and rapid sedation. Preserves respiratory drive, airway protective reflexes when used in appropriate dosages. Lower dose of ketamine is advocated for hemodynamically compromised patients.
	IM: 3-4 mg/kg	3-10 min	15-60 min	

Contd...

Ketamine may decrease or protect against bronchospasm and improve ventilation in asthmatics. Ketamine adverse effects include increased systemic, intracranial, and intraocular pressures, hallucinogenic emergence reactions, laryngospasm and excessive airway secretion. Chloral hydrate (hypnotic agent) may have paradoxical excitatory effect. Propofol may decrease cardiac output and cause severe hypotension. It is contraindicated in patients with history of allergy to egg or soybean. Nitrous oxide is most useful in cooperative patients (>6-8 years). Side effects include hypoxemia after its discontinuation; all patients should breath 100% O₂ for at least 5 min. after its discontinuation. It is relatively contraindicated in patients with air-leak syndromes like (pneumothorax) or closed air spaces (bowel obstruction).

Chloral hydrate	PO, PR: 25-100 mg/kg; max 2 gms.	15-30 min	2-3 hours
Ketorolac	IV, IM: 0.5-1 mg/kg	10-15 min	3-6 hours
Propofol	IV: 0.5-1 mg/kg; may be repeated in 0.5 mg/kg boluses; may be given as a titrated continuous infusion of 25-100 mcg/kg/min	1-2 min	3-5 min
Nitrous-oxide	25-50% of NO with O ₂		

prospectively collected hospital-based pediatric sedation/anesthesia encounters in which 77 percent of the sedations were performed by anesthesiologists, emergency physicians, or intensivists. The incidence of adverse events (primarily transient oxygen desaturation, vomiting, and excessive secretions) was three percent. There were no deaths. One patient was successfully resuscitated from cardiac arrest.²¹

Assessment and Triage of a Sick Child in Emergency Room

Suresh Gupta

There are many reasons for which a sick child may visit pediatric office or pediatric emergency room. Assessment of pediatric patients presents a unique challenge whose size may vary from the newly born through adolescence. In a general emergency department (ED), the pediatric patients account for 25 to 30 percent of the total visits. Although most pediatric visits to the ED may not be life-threatening but significant number of children may have serious or potentially serious underlying disease. There are wide varieties of etiology which can lead to these serious and life-threatening pediatric emergencies. The management of these sick children requires a basic understanding of the unique age specific anatomic, physiologic, immunologic, and developmental differences on the part of health care provider. Moreover, the emergency care does not stop or start at the ED level, ED is only one of the important components of integrated emergency medical system. Most of the sick children are initially seen in small community hospitals and for definitive care at tertiary hospitals, inter-facility transport system is required.

Respiratory emergencies and trauma are the most common causes for visits to an ED. The common problems include acute respiratory infection, fever, otitis media and other head and neck infections, enteritis, and minor cuts and contusions. Trauma is one of the most common causes of serious morbidity and mortality in children younger than 15 years. Most of these injuries are unintentional injuries, predictable and preventable. Irrespective of the underlying etiology, the care of critically ill or injured children should always focus on two physiologic events: shock and respiratory failure. This chapter focuses on the role of the emergency physician in recognizing, assessing and triaging children needing emergency care.

ANATOMICAL, PHYSIOLOGICAL AND DEVELOPMENTAL ISSUES IN ASSESSMENT

The assessment of a child requires attention to a variety of anatomic, physiologic, and developmental differences that vary with the age. For example, the infant have large surface area-to-weight ratio, making them more prone to temperature instability and highlights the importance of a neutral thermal environment during assessment and management. The relatively large head-to-body ratio and the small, weak neck make the children more prone to head injuries. Soft and pliable growing ribs of children allow the blunt trauma to cause injury to internal organs of chest and abdomen with negligible or no external signs. Growth plates are the weakest part of growing bones rather than surrounding ligaments. So, in a growing child, the sprains are uncommon and physeal fractures are more common. The smaller airways of infants and young children are more prone to obstruction from secretions with resultant more rapid respiratory distress to failure. Compensatory mechanisms of young children provide them extra protection from decompensated shock. Recognition and justification for abnormal vital signs is one of the keys to success in the treatment of the ill patient. It is crucial for the provider to be familiar with these different values of the vital signs as these vary with age. Moreover the vital signs at one given point in time may be quite difficult to interpret. Repeated serial measurement of vital signs will provide a more accurate assessment of the physiologic status of child.

The assessment of any sick child should always take into account the age-related differences in motor function, problem-solving, language, and social/adaptive milestones. During the neonatal period the discomfort is

usually nonspecific, and the cause of the irritability or crying may be difficult to interpret. A mother's "sense" of her child is often accurate and should be considered seriously. By 2 to 3 months, an infant has a social smile and responds to a friendly voice. Lack of appropriate social interaction can be worrisome. An infant with a glassy-eyed, "nobody home" stare can be easily distinguished. Normal behavior for a 6 month old baby includes any expression of curiosity or anxiety, such as crying. If a 6 month baby does not acknowledge your presence, it is a matter of concern. Children older than 6 months will exhibit stranger anxiety. So, the children at this age should preferably be examined in the lap of the caregiver. During the toddler and preschool age, child has more extensive receptive language than expressive language and can pick up fears and concerns. Praise, reassurance and allowing the child to control some part his experience will help in maintaining the rapport with the child. As child reaches school age, the power of reasoning and negotiating become more mature. So, it is important to explain procedures, answer questions, and address fears and concerns honestly. With adolescence comes independence and autonomy but may not anticipate consequences. Privacy and confidentiality should always be respected and should be involved in decision making.

EMERGENCY ASSESSMENT OF PEDIATRIC PATIENTS

Emergency assessment focuses on identification of children at risk for decompensation and deterioration. The initial assessment begins with examination of respiratory effort, circulation of the skin and mental status of the child to make a first impression whether the child is "sick or not sick" The pediatric assessment triangle (PAT) (Fig. 1) is one of the simple clinical tools which can be used to assess children of all ages, identify abnormal cardiopulmonary physiology, and define the urgency and need for lifesaving interventions.

THE INITIAL ASSESSMENT: PEDIATRIC ASSESSMENT TRIANGLE

The initial assessment of the child condition is made by observing the child from a distance for visual and auditory hints even before touching him/her. The three arms of this initial assessment or PAT are: (1) A: appearance, (2) B: work of breathing, and (3) C: circulation to the skin. This quick assessment in first few seconds will help the health care provided in making a sense whether the child is sick or not sick.

Appearance: By looking at the child from a distance, one can make out whether the child is irritable, drowsy, lethargic, or interacting with the surrounding normally. The commonly used mnemonic TICLS: Tone, Interactiveness, Consolability, look/gaze, and speech/cry is a good way

to be more objective for this assessment. The abnormal assessment can result from inadequate brain perfusion like in shock or hypoxia due to respiratory problem or due to primary neurological insult which may be traumatic or nontraumatic. A normal appearance indicates that ventilation, oxygenation, and brain perfusion are at least adequate.

Work of breathing: Very often, observing the child from a distance will provide better clue regarding work of breathing rather than examining a crying child. The type of audible abnormal airway sounds such as grunting, wheezing, stridor, and snoring will help in deciding the underlying cause of respiratory distress. Observing for other abnormalities like sniffing position, tripod position, nasal flaring, head bobbing, see-saw breathing, presence of inter-costal, supraclavicular, and substernal retractions will also be useful to infer the cause and severity of airway obstruction.

Circulation to the skin: Visual examination of the skin can be used quickly to assess the peripheral perfusion. A pale skin with rapid heart rate is strongly suggestive of shock or blood loss or severe anemia. Mottling of skin reflects loss of small vessel integrity and is an ominous sign. It is important not to confuse cutis marmorata with mottling in young infants. Cyanosis is an indication of respiratory failure or decompensated shock unless the child is cyanotic as a result of chronic primary cardiopulmonary problems or congenital heart disease.

By integrating the information gained through this pediatric assessment triangle (appearance, work of breathing and circulation to skin), an initial impression regarding physiological status of the child can be made and acuity of the problem may also be judged (Table 1).

Primary Assessment

After a quick initial evaluation through the pediatric assessment triangle, the health provider begins the primary assessment. This part of evaluation focuses on following components in an orderly and stepwise fashion.

- A: Airway
- B: Breathing
- C: Circulation
- D: Disability
- E: Exposure
- F: Family

While interpreting the vital signs in children, one should always keep in mind the age appropriate standards of vital parameters and trends are more important than individual single reading. Assessment of the airway involves checking for the patency and the ability to maintain independently or with airway adjuvant. Breathing evaluation focuses on respiratory rate and efforts and oxygenation. The health care provider must resolve issues related to each step before progressing to the next one. The AVPU (alert, verbal, painful, unresponsive) scale is

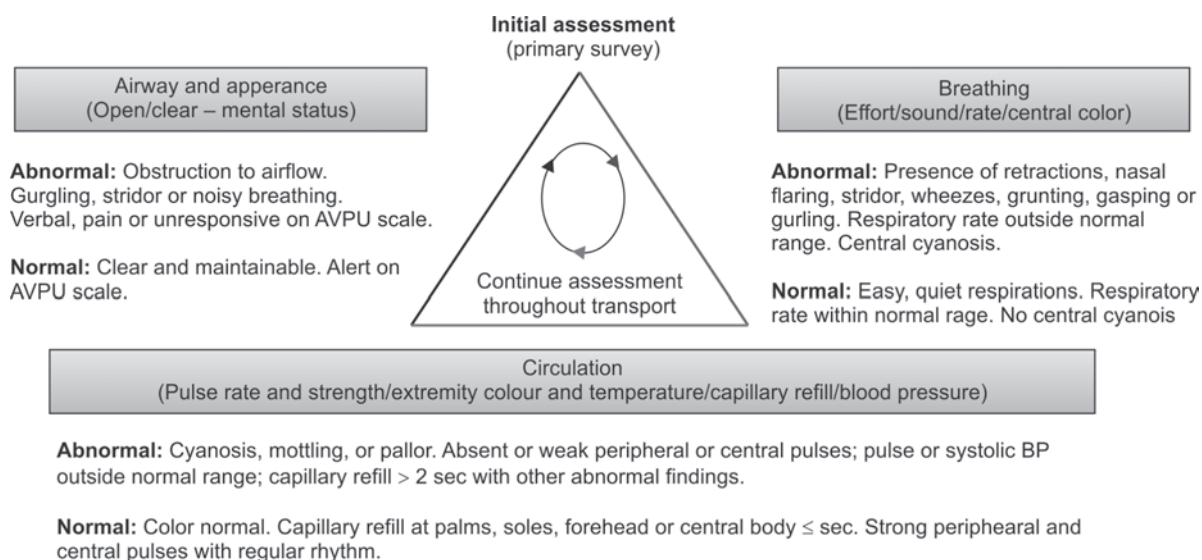

Fig. 1: Pediatric assessment triangle (PAT)

Table 1: Pediatric assessment triangle and its interpretation

<i>Physiological status</i>	<i>Appearance</i>	<i>Work of breathing</i>	<i>Circulation to skin</i>
Respiratory distress	Normal	Abnormal	Normal
Respiratory failure	Abnormal	Abnormal	Normal/abnormal
Compensated shock	Normal	Normal	Abnormal
Decompensated shock	Abnormal	Normal/abnormal	Abnormal
Brain injury/dysfunction	Abnormal	Normal	Normal
Cardiopulmonary failure	Abnormal	Abnormal	Abnormal

a simple clinical tool to assess the disability or neurological status whether the child is alert, responsive to verbal commands, responsive only to painful stimuli, or unresponsive. Exposure of children should be done with the parent's assistance while maintaining the modesty and respect for the child. A neutral thermal environment should be maintained to avoid hypothermia and heat loss.

Secondary and Tertiary Assessment

After primary assessment and initial stabilization, a more detailed examination of the child is done from head to toe. At the same time, a brief history is obtained from the family or the available care provider. A mnemonic of this brief history is SAMPLE: Signs/symptoms, allergies, medications, past medical problems, last meal and events preceding the injury/illness. Interviewing a child and parents in emergency room is an art as the parents who bring children to an ED for care usually perceive that their child has an emergency. So, it is important to treat the family with respect, gentleness, and kindness to ensure trusting patient-doctor relationship. In an emergency setting, the chief complaint and present illness are the main focus for

information gathering, so always begin the interview by asking "What brings you and your child to the emergency department today?" The examination of a child should be performed in the least hurtful manner while concentrating on most important components initially and doing fear-provoking part at the end of examination. There is no need to follow a stepwise fashion from head to toe. Infants and toddlers are always most comfortable and cooperative when examined in the parent's lap.

SPECIFIC SITUATIONS AND CHILDREN WITH SPECIAL HEALTH CARE NEEDS

Trauma is a special situation where initial assessment starts with a primary survey that includes careful assessment of the airway, adequacy of oxygenation and ventilation, as well as a search for signs of circulatory compromise. The most important priority in these cases is to identify life-threatening abnormalities and start appropriate resuscitation efforts. After this, a careful and detailed secondary trauma survey is necessary to identify subtle but potentially life-threatening injuries. Evaluation of the cervical spine is a critical part of pediatric trauma assessment to look

for the risk of spinal injury. While the secondary trauma survey is systematically performed, continued attention is maintained on the PAT and primary survey to identify any ongoing bleeding or progressing respiratory problems.

Another group of children who need evaluation in a different manner are those with special health care needs. These children account for a large number of emergency and urgent ED visits. Clinical assessment can be difficult in a child with developmental delay or significant neurologic problems. In such cases pediatric assessment triangle has its own limitation. In these children, the healthcare provider should take the help of the caretaker to know the baseline neurological status of the child. The subtle observation made the caretaker usually provide important clues to a potentially serious illness or complications. It is always better to seek specialty consultation from providers who are familiar with children who have special health care needs.

PEDIATRIC EMERGENCY TRIAGE

Large numbers of children visit the general or pediatric emergency department. Providing the medical care to these pediatric patients in the order of attending may lead to long waiting times for seriously ill patients and increased risk of morbidity and mortality. So, it is important to prioritize patients who are seriously ill and would be at increased risk of morbidity or even mortality due to delay in the initiation of treatment. The aim of triage is to determine and classify the clinical priority of patients visiting the ED. During a short assessment the nurse will identify signs and symptoms that determine the patient's

urgency. The physician will see the patients in order of their urgency level. Patients requiring immediate care are identified. Moreover, patients are identified who can safely wait longer or who can be seen by another caregiver such as the general practitioner or nurse practitioner. Triage systems are developed by expert opinion with the lowest level of evidence, and are mainly based on the adult population visiting the ED. Several studies have investigated the reliability and validity of triage systems in children. The Pediatric Canadian Triage and Acuity Scale (PedC-TAS) was especially modified for the pediatric population. Although different criteria per triage system are used, they all sort patients into five urgency categories except for the WHO triage which divides the children in three categories (Table 2).

The commonly used triage systems in pediatric emergency include:

- Manchester triage system (MTS)
- Emergency severity index (ESI)
- Pediatric Canadian Triage and Acuity Score (pedC-TAS)
- Australasian triage scale (ATS)
- The triage suggested by WHO manual of emergency care of children.

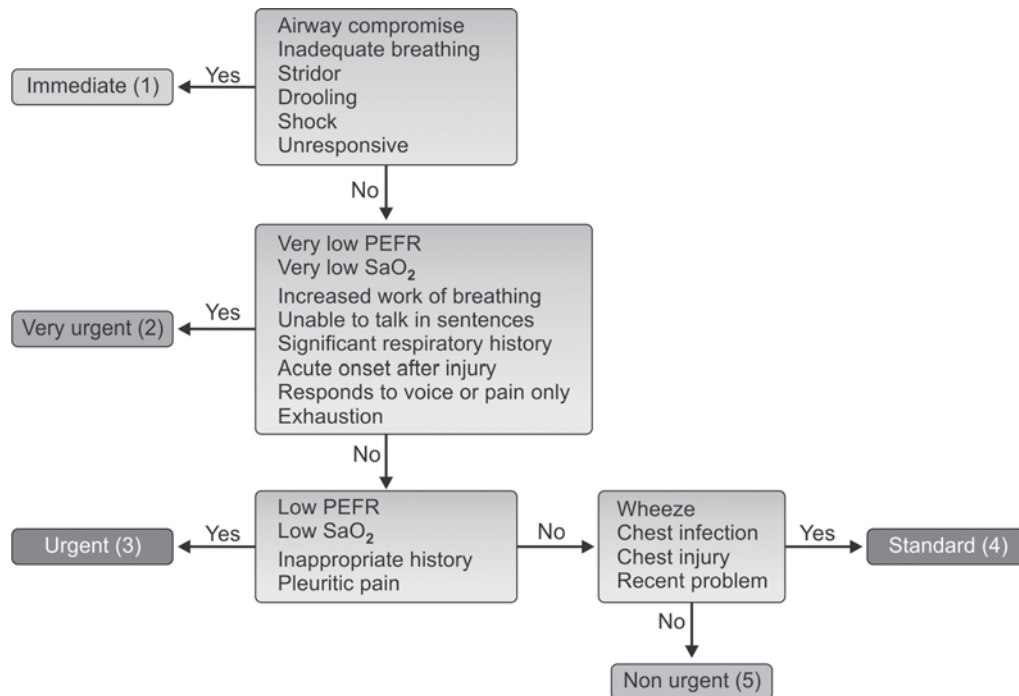

Manchester triage system (MTS): The first version was published in 1997 followed by second version in 2006 (Flow chart 1). The MTS contains 52 flow charts presenting different presenting problems. Some flowcharts are specific for children, such as 'Worried parent', 'Abdominal pain in children', 'Crying baby', 'Shortness of breath in children', 'Limping child', 'Unwell child' and 'Irritable child'. The

	Level 3: Urgent (Yellow)	Level 3: 60 minutes
	Level 4: Standard (Green)	Level 4: 120 minutes
	Level 5: Nonurgent (Blue)	Level 5: 240 minutes
Canadian triage and acuity scale (CTAS) (Canada)	Level 1: Resuscitation	Level 1: 0 minutes
	Level 2: Emergent	Level 2: 15 minutes
	Level 3: Urgent	Level 3: 30 minutes
	Level 4: Less Urgent	Level 4: 60 minutes
	Level 5: Nonurgent	Level 5: 120 minutes

(Australasian College for Emergency Medicine, 2002; Manchester triage group, 1997; Canadian Association of Emergency Physicians, 2002)

Flow chart 1: Manchester triage system flow chart shortness of breath in children

flow charts contain general as well as specific discriminators, which are presenting signs or symptoms of the patient. General discriminators are life threat, pain, hemorrhage, conscious level, temperature and acuteness. Specific discriminators are related to the presenting problems such as 'Increased work of breathing' (flow chart 'Shortness of breath in children') or 'Persistent vomiting' (flow chart 'Abdominal pain in children'). The selected discriminator leads to an urgency level. Medical care should be delivered immediately for level 1, within 10 minutes for level 2, within 60 minutes for level 3, within 120 minutes for level 4 and within 240 minutes for level 5. Some of the studies have found low validity for a subgroup of patients such as young patients, patients with a nontraumatic presenting problem and older patients with fever.

Canadian triage and acuity scale (CTAS): In 2001, a specific guideline to triage children was added to the CTAS, (pedCTAS). Per presenting problem, specific criteria are provided to allocate patients to different urgency levels. For example, children presenting with respiratory distress, for level 1 signs are: inability to speak, cyanosis, lethargy or confusion, tachycardia or bradycardia, and hypoxemia with $SpO_2 < 90$ percent. For level 2, the signs audible stridor, intermittent respiratory distress and audible wheezing, tachypnea, or cough are listed in order to select patients with respectively upper respiratory distress, congenital vascular anomalies and foreign bodies or lower airway concerns. Level 3 is for patients with moderate respiratory distress such as patients with pneumonia, bronchiolitis or croup. Level 4 and 5 do not contain criteria for

patients with respiratory distress. Medical care should be delivered immediately for level 1, within 15 minutes for level 2, within 30 minutes for level 3, within 60 minutes for level 4 and within 120 minutes for level 5. Table 3 lists the 10 most common causes for triage level I and level II visits in children hospital at Colorado.

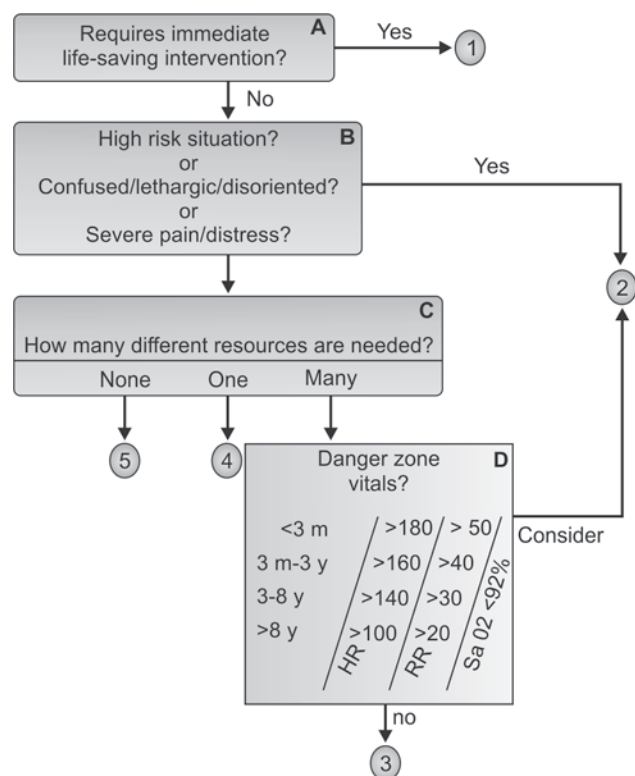

Emergency severity index (ESI): The ESI is a 5-level triage system, developed in the United States. Level 1 stands for the highest acuity level and level 5 for the lowest acuity. Patients requiring immediate lifesaving interventions are allocated into level 1 and must be seen immediately. Patients in a high risk situation, who are confused, lethargic, disoriented, have severe pain or distress or have deviated vital signs/PO are attributed to level 2. A physician should see these patients within ten minutes. Level 3 is for patients who are expected to require two or more resources. Level 4 is attributed if one resource is expected to be required and 5 if no resources are expected to be required. Resources can be diagnostics (for example, lab tests, ECG, X-rays, CT scan etc), treatment (for example IV fluids, laceration repair) or specialty consultation. Patients triaged as level 3 to 5 can safely wait for several hours (Flow chart 2).

In the fourth version of the ESI, a specific flowchart for children with fever was added. It uses age, the height of fever, the cause of fever and whether the child is immunized to determine urgency. Children younger than 28 days with a temperature $> 38.0^\circ\text{C}$ are allocated to level 2. Children with fever aged 28 days – 3 months are assigned to level 2 or 3, depending on the hospital's institutional

protocol. Children aged 3 to 36 months who are under immunized or who have no obvious source of fever and a temperature $>39.0^{\circ}\text{C}$ are allocated to level 3.

Australasian triage scale (ATS): This was formerly known as the National Triage Scale. The ATS provides criteria per urgency level. Most criteria are general but three criteria are specific for children: shocked child/infant should be allocated to level 1, all 'stable neonates' are allocated to level 3 as well as 'children at risk'.

Flow chart 2: Emergency severity index (ESI): Triage algorithm

WHO pocket book of hospital care for children: This manual also provides a simple and rapid method of screening sick children soon after their arrival in hospital. The children are categorized in three groups: (1) Children with emergency signs, (2) Children with urgent signs and (3) Non-urgent cases

Those with emergency signs: These children require immediate emergency treatment. The emergency signs include:

- Obstructed breathing
- Severe respiratory distress
- Central cyanosis
- Signs of shock (cold hands; capillary refill longer than 3 seconds; weak, fast pulse)
- Coma
- Convulsions
- Signs of severe dehydration in a child with diarrhea (lethargy, sunken eyes, very slow return after pinching the skin—any two of these).

Children with emergency signs require immediate treatment to avert death. Any child coming to the hospital should be checked immediately of any emergency signs. Checking for emergency signs is done in two steps:

- *Step 1:* If there is any airway or breathing problem, start immediate treatment to restore breathing.
- *Step 2:* Quickly determine if the child is in shock or unconscious or convulsing, or has diarrhea with severe dehydration.

If emergency signs are found, call an experienced health professional to help if available, but do not delay starting the treatment. Stay calm and work with other health workers who may be required to give the treatment, because a very sick child may need several treatments at once. The most experienced health professional should continue assessing the child, to identify all underlying problems and develop a treatment plan. Carry out

Table 3: Ten common causes of triage level 1 and Triage level 2 in a children

Triage level 1	Triage level 2
Trauma	Respiratory distress
Seizures	Suspected sepsis/meningitis
Respiratory failure	Trauma/injury
Altered consciousness	Sickle cell disease complications
Sepsis	Diabetes complications
Cardiac problem	Genitourinary complaints
Diabetic ketoacidosis	VP shunt complications
Toxic ingestion	Seizures
SIDS/CPR	Hypovolemic dehydration
Hypovolemic shock	Oncology patient with fever

CPR, cardiopulmonary resuscitation; SIDS, sudden infant death syndrome; VP, Ventriculoperitoneal

emergency investigations (blood glucose, blood smear, hemoglobin). Send blood for typing and cross-matching if the child is in shock, or appears to be severely anemic, or is bleeding significantly. After giving emergency treatment, proceed immediately to assessing, diagnosing and treating the underlying problem.

Those with priority signs: If no emergency signs are found, check for priority signs. The priority signs identify children who are at higher risk of dying. These children should be given priority while waiting in the queue so that they can be assessed and treated without delay. The priority signs include:

- Tiny baby: any sick child aged under 2 months
- Temperature: child is very hot
- Trauma or other urgent surgical condition
- Pallor (severe)
- Poisoning
- Pain (severe)
- Respiratory distress
- Restless, continuously irritable, or lethargic
- Referral (urgent)
- Malnutrition: visible severe wasting
- Edema of both feet
- Burns (major).

The above can be remembered with the help of “3TPR MOB”. These children need prompt assessment (no waiting in the queue) to determine what further treatment is needed. Move the child with any priority sign to the front of the queue to be assessed next. If a child has trauma or other surgical problems, get surgical help where available.

Nonurgent cases: The children having neither emergency nor priority signs are categorized as nonurgent cases.

These are to be attended by after taking care of children having emergency or priority signs.

Various studies have tried to compare the validity and reliability of these triage systems for children. A recent review article based on search in Pubmed and Cochrane on studies on reliability and validity of triage systems in children concluded that the MTS and pedCTAS both seem valid to triage children. Available studies show that reliability of the MTS is good, is moderate to good for the ESI, moderate for the pedCTAS and poor to moderate for the ATS.

Emergency Cardiopulmonary Resuscitation

Suresh Gupta

When cardiac arrest or life-threatening emergencies occur, prompt and skillful response can make the difference between life and death and between intact survival and debilitation. Since 2000, researchers from the International Liaison Committee on Resuscitation (ILCOR) member councils have evaluated resuscitation science in 5-year cycles. The conclusions and recommendations of the 2005 International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care with Treatment Recommendations were published at the end of 2005. The most recent International Consensus Conference was held in Dallas in 2010. This article is based on the current recommendations and guidelines for pediatric basic life support (BLS) and pediatric advanced life support (PALS). Pediatric advanced life support always begins with a good basic life support which is continued from out of hospital settings to the emergency room. The core concepts of BLS are outlined first before discussing the PALS.

BASIC LIFE SUPPORT IN CHILDREN

Introduction

Early recognition and treatment of sudden cardiac arrest improves survival for children and adults.¹⁻³ Basic life support (BLS) involves a systematic approach to initial patient assessment, activation of emergency medical services, and the initiation of cardiopulmonary resuscitation (CPR), including defibrillation. Key components of effective CPR include adequate ventilation and chest compressions. BLS can be performed by trained lay persons, as well as by health care providers. Bystander CPR has been associated with a greater than 70 percent chance of neurologically intact survival after respiratory arrest in children and is a key component to achieving optimal survival following a sudden witnessed cardiac collapse due to

a ventricular arrhythmia.⁴ Based upon extensive review of clinical and laboratory evidence, the American Heart Association (AHA) and the ILCOR published updated guidelines for pediatric BLS in 2010.⁴⁻⁷ For the purposes of these guidelines, a newborn is defined as from birth to hospital discharge, an infant is younger than one year of age, and a child is from one year to start of puberty. The guidelines are designed to be simple, practical, and effective. Changes for infants and children from the previous basic life support guidelines of 2005 include new criteria for the initiation of CPR, compressions prior to airway and breathing for infants and children in cardiac arrest (CAB instead of ABC), and evidence-based reaffirmation of conventional cardiopulmonary resuscitation (CPR) as preferred to compression only CPR (Table 1).

BASIC LIFE SUPPORT SEQUENCE

Before beginning basic life support (BLS), rescuers must ensure that the scene is safe for them and the victim. The next steps in BLS are activating emergency medical services (EMS), getting an automated external defibrillator (AED), and starting cardiopulmonary resuscitation (CPR). *Activate EMS:* For activating EMS, the guidelines recommend the following in infants and children for health care providers⁴⁻⁷:

- If two or more rescuers present
 - For unwitnessed and witnessed cardiac arrests with two or more rescuers present, initiation of CPR, activation of the emergency response system, and getting an automated external defibrillator (AED) occur simultaneously. CPR should be performed for two minutes (five cycles) before using an AED in a patient with an unwitnessed arrest based on limited evidence in adults that even for prolonged arrest from ventricular fibrillation (VF), an initial

Table 1: 2010 American Heart Association Guidelines for CPR and key changes in basic life support

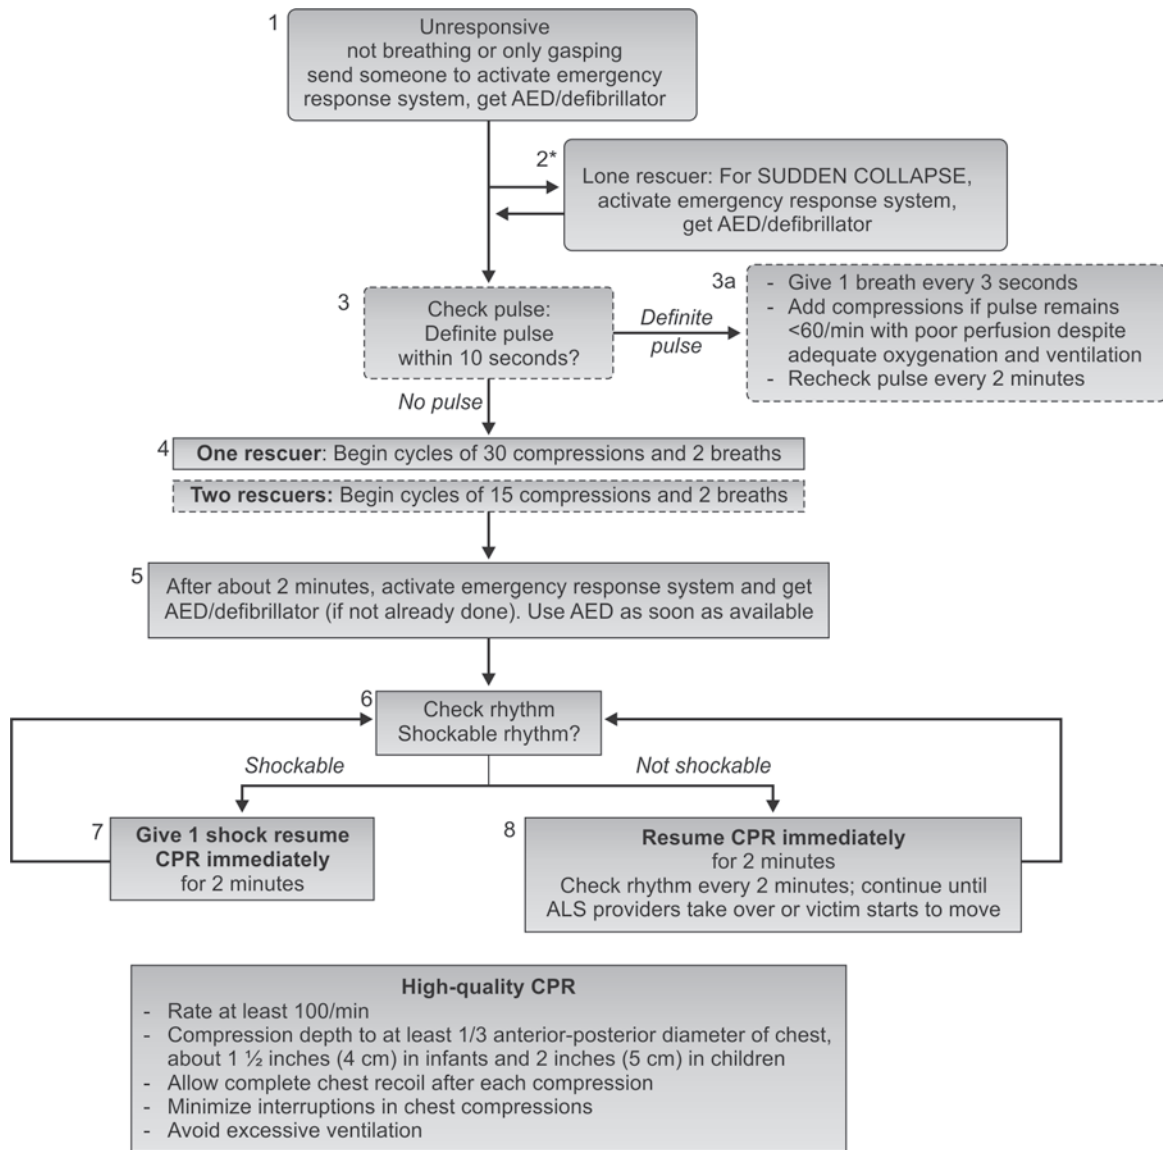

<i>2010 Recommendation</i>	<i>2005 Recommendation</i>	<i>Explanation</i>
<i>Pediatric basic life support</i>		
Initiate CPR for infants and children with chest compressions rather than rescue breaths (C-A-B) rather than A-B-C). CPR should begin with 30 compressions (any lone rescuer) or 15 compressions (for resuscitation of infants and children by two health care providers) rather than with two ventilations.	Cardiopulmonary resuscitation was initiated with opening of the airway and the provision of 2 breaths before chest compressions.	This proposed major change in CPR sequencing to compressions before ventilations (C-A-B) led to vigorous debate among experts in pediatric resuscitation. Because most pediatric cardiac arrests are asphyxial, rather than sudden primary cardiac arrests, both intuition and clinical data support the need for ventilations and compressions for pediatric CPR. However, pediatric cardiac arrests are much less common than adult sudden (primary) cardiac arrests, and many rescuers do nothing because they are uncertain or confused. Most pediatric cardiac arrest victims do not receive any bystander CPR, so any strategy that improves the likelihood of bystander action may save lives. Therefore, the C-A-B approach for victims of all ages was adopted with the hope of improving the chance that bystander CPR would be performed. The new sequence should theoretically only delay rescue breaths by about 18 seconds (the time it takes to deliver 30 compressions) or less (with 2 rescuers).
To achieve effective chest compressions, rescuers should compress at least one third of the anterior-posterior diameter of the chest. This corresponds to approximately 1½ inches (about 4 cm) in most infants and about 2 inches (5 cm) in most children.	Push with sufficient force to depress the chest approximately one-third to one-half the anterior-posterior diameter of the chest.	Evidence from radiologic studies of the chest in children suggests that compression to one half the anterior-posterior diameter may not be achievable. However, effective chest compressions require pushing hard, and based on new data, the depth of about 1½ inches (4 cm) for most infants and about 2 inches (5 cm) in most children is recommended.
For infants, a manual defibrillator is preferred to an AED for defibrillation. If a manual defibrillator is not available, an AED equipped with a pediatric dose attenuator is preferred. If neither is available, an AED without a pediatric dose attenuator may be used.	Data have shown that AEDs can be used safely and effectively in children 1 to 8 years of age. However, there are insufficient data to make a recommendation for or against using an AED in infants < 1 year of age.	Newer case reports suggest that an AED may be safe and effective in infants. Because survival requires defibrillation when a shockable rhythm is present during cardiac arrest, delivery of a high-dose shock is preferable to no shock.

period of CPR improves the likelihood of successful defibrillation. This approach is the same as for adults with cardiac arrest.

- If the lone rescuer, the sequence varies:
 - If the cardiac arrest is witnessed, the lone rescuer should first activate the emergency response system, obtain an AED, and then start CPR. This approach is the same as for adults with cardiac arrest.
 - If the cardiac arrest is unwitnessed, the lone rescuer should first perform two minutes of CPR, activate the emergency response system, and then obtain an

AED. CPR is recommended initially for infants and children with an unwitnessed cardiac arrest being cared for by a lone rescuer because most pediatric arrests are likely to be asphyxial. This approach differs from that recommended for adults.

- Initiate CPR—The steps of cardiopulmonary resuscitation (CPR) are opening the airway, providing ventilations (rescue breaths), and performing chest compression. The sequence of the actions of CPR for infants and children should be performed by health care providers is as follows (Flow chart 1):

Flow chart 1: Pediatric BLS algorithm for health care providers: 2010 guidelines

AED: Automated external defibrillator; BLS: Basic life support; CPR: Cardiopulmonary resuscitation.

* The boxes bordered by dotted lines are performed by health care providers and not by lay rescuers. Source Pediatric Basic Life Support: 2010. American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. © 2010 American Heart Association, Inc.

- Initiate CPR in an infant or child who is unresponsive and not breathing (or only gasping).
 - If there is no pulse or it is not definitively identified within 10 seconds, then start compressions before performing airway or breathing maneuvers. After 30 compressions (15 compressions if two rescuers) open the airway and give two breaths.
 - If a definite pulse is found within 10 seconds, provide ventilation only
 - If the pulse is ≥ 60 beats per minute (bpm), continue ventilation
 - If the pulse is < 60 bpm, add chest compressions to ventilation
- High quality CPR focuses on the effective delivery of chest compressions and avoidance of excessive ventilation.

VENTILATION

Ventilations can be provided with mouth-to-mouth, mouth-to-nose, or with a bag and mask. Evidence in adults and animals suggest that hyperventilation is associated with increased intrathoracic pressure and decreased coronary and cerebral perfusion. Based on these data following recommendations are made.^{4,8}

- Each rescue breath should be delivered over one second.
- The volume of each breath should be sufficient to see the chest wall rise.
- A child with a pulse ≥ 60 bpm who is not breathing should receive one breath every three to five seconds (12 to 20 breaths per minute).
- Infants and children who require chest compressions should receive two breaths per 30 chest compressions for a lone rescuer and two breaths per 15 chest compressions for two rescuers.
- Intubated infants and children should be ventilated at a rate of 8 to 10 breaths per minute without any interruption of chest compressions.

CHEST COMPRESSIONS

The new guidelines emphasize the importance of hard and fast chest compression, with full chest recoil and minimal interruptions.⁵ Chest compressions should be performed over the lower half of the sternum.^{4,6,9} Compression of the xiphoid process can cause trauma to the liver, spleen, or stomach, and must be avoided. The effectiveness of compressions can be maximized by attention to the following:

- The chest should be depressed at least one-third of its anterior-posterior diameter with each compression (approximately 4 cm (1 ½ inches) in most infants and 5 cm (2 inches) in most children).
- The optimum rate of compressions is at least 100 per minute. Each compression and decompression phase should be of equal duration.
- The sternum should return briefly to its normal position at the end of each compression, allowing the chest to recoil fully.
- A smooth compression-decompression rhythm, with minimal interruption, should be developed.
Infants — Chest compressions for infants (younger than one year) may be performed with either two fingers or with the two thumb-encircling hands technique.
- Two fingers technique: This is recommended when there is a single rescuer.^{4,7} Compressions are performed with index and middle fingers, placed on the sternum just below the nipples. Because of the infant's large occiput, slight neck extension and the placement of a hand or rolled towel beneath the upper thorax and shoulders may be necessary to ensure that the work of compression is focused on the heart.

- Two thumb-encircling hands technique: It is suggested when there are two rescuers.⁴ The thorax is encircled with both hands and cardiac compressions are performed with the thumbs. The thumbs compress over the lower half of the sternum, avoiding the xiphoid process, while the fingers are spread around the thorax.^{4,7}

Children: For children (from one year until the start of puberty), compressions should be performed over the lower half of the sternum with either the heel of one hand or with two hands, as for adult victims.

COMPRESSION TO VENTILATION RATIO

Chest compressions in infants and children should always be accompanied by ventilation for infants and children who remain pulseless after the initial sequence of compressions.⁴⁻⁷ However, every effort should be made to avoid excessive ventilation and to limit interruptions of chest compressions to less than ten seconds.

- For lone rescuers, two ventilations should be delivered during a short pause at the end of every 30th compression.
- For two rescuers, two ventilations should be delivered at the end of every 15th compression. The compression to ventilation ratio for newborns is 3 to 1.
- Once the trachea is intubated, ventilation and compression can be performed independently. For infants and children, ventilations are given at a rate of 8 to 10 per minute. Compressions are delivered at a rate of 100 per minute without pauses. Compression to ventilation ratios of 30 to 2 and 15 to 2 are recommended to minimize interruption and for ease of teaching and retention.^{4,5} Coordination of compression and ventilation may be facilitated by counting compressions aloud rousing an audio-prompted rate guide.¹⁰

Conventional versus compression-only CPR: Although compression-only CPR (COO-CPR) for bystanders is suggested in limited situations in adults with cardiac arrest, conventional CPR is recommended in infants and children, because cardiac arrest in this population is more commonly due to hypoxia when compared to adults.⁴⁻⁶

AUTOMATED EXTERNAL DEFIBRILLATOR

According to newer guidelines, if a manual defibrillator is not available, an automated external defibrillator (AED) is used as soon as possible for infants and children who experience a witnessed cardiac arrest.⁴⁻⁷ For patients with unwitnessed arrest, CPR should be performed for two minutes (five cycles) prior to using an AED. For infants and children <8 years of age, an AED with a pediatric dose attenuating system should be used whenever possible. However, if a manual defibrillator or an AED with a pediatric dose attenuating system is not available, then use of an AED without a dose attenuator is advised.^{4,7}

PEDIATRIC ADVANCED LIFE SUPPORT

Introduction

The American Heart Association (AHA) pediatric advanced life support (PALS) program provides a structured approach to the assessment and treatment of the critically ill pediatric patients.¹¹ The AHA guidelines for pediatric resuscitation were updated in year 2010 to include the new evidence from a variety of sources ranging from large clinical trials to animal models¹² (Table 2). The components of pediatric advanced life support include

- Overview of assessment
- Recognition and management of respiratory distress and failure

- Recognition and management of shock

- Review of pharmacology

Overview of Assessment

A rapid assessment facilitates rapid evaluation and intervention for life-threatening conditions. In infants and children, most cardiac arrests result from progressive respiratory failure and/ or shock. The rapid assessment aims at recognizing the respiratory failure before progression to cardiac arrest. The evaluation includes:

Table 2: 2010 American Heart Association Guidelines for CPR and key changes in pediatric advanced life support		
2010 Recommendation	2005 Recommendation	Explanation
<i>Pediatric advanced life support</i>		
Specific resuscitation guidance has been added for management of cardiac arrest in infants and children with single-ventricle anatomy, Fontan or hemi-Fontan/bidirectional Glenn physiology, and pulmonary hypertension.	These topics were not addressed in the 2005 guidelines.	Specific anatomical variants with congenital heart disease present unique challenges for resuscitation.
Although there have been no published results of prospective randomized pediatric trials of therapeutic hypothermia, based on adult evidence, therapeutic hypothermia (to 32°C to 34°C) may be beneficial for adolescents who remain comatose after resuscitation from sudden witnessed out-of-hospital VF cardiac arrest. Therapeutic hypothermia (to 32°C to 34°C) may also be considered for infants and children who remain comatose after resuscitation from cardiac arrest.	Based on extrapolation from adult and neonatal studies, when pediatric patients remain comatose after resuscitation, consider cooling them to 32°C to 34°C for 12 to 24 hours.	Additional adult studies have continued to show the benefit of therapeutic hypothermia for comatose patients after cardiac arrest, including those with rhythms other than VF. Pediatric data are needed.
The new guidelines have added this topic: When a sudden, unexplained cardiac death occurs in a child or young adult, obtain a complete past medical and family history (including a history of syncopal episodes, seizures, unexplained accidents/drowning, or sudden unexpected death at <50 years of age) and review previous ECGs. All infants, children, and young adults with sudden, unexpected death should, where resources allow, have an unrestricted complete autopsy, preferably performed by a pathologist with training and experience in cardiovascular pathology. Tissue should be preserved for genetic analysis to determine the presence of channelopathy.	This was not addressed in the previous guidelines.	There is increasing evidence that some cases of sudden death in infants, children, and young adults may be associated with genetic mutations that cause cardiac ion transport defects known as channelopathies. These can cause fatal arrhythmias, and their correct diagnosis may be critically important for living relatives.

Contd....

Suctioning immediately after birth should be reserved for babies who have an obvious obstruction to spontaneous breathing or require positive-pressure ventilation.

The person assisting delivery of the infant should suction the infant's nose and mouth with a bulb syringe after delivery of the shoulders but before delivery of the chest. Healthy, vigorous newly born infants generally do not require suctioning after delivery. When the amniotic fluid is meconium stained, suction the mouth, pharynx, and nose as soon as the head is delivered (intrapartum suctioning) regardless of whether the meconium is thin or thick.

There is no evidence that active babies benefit from airway suctioning, even in the presence of meconium, and there is evidence of risk associated with this suctioning. The available evidence does not support or refute the routine endotracheal suctioning of depressed infants born through meconium-stained amniotic fluid.

The recommended compression-to-ventilation ratio for newborns remains 3:1. If the arrest is known to be of cardiac etiology, a higher ratio (15:2) should be considered.

There should be a 3:1 ratio of compressions to ventilations.

The optimal compression-to-ventilation ratio remains unknown. The 3:1 ratio for newborns facilitates provision of adequate minute ventilation, which is considered critical for the vast majority of newborns who have an asphyxial arrest. The consideration of a 15:2 ratio (for 2 rescuers) recognizes that newborns with a cardiac etiology of arrest may benefit from a higher compression-to-ventilation ratio.

There is increasing evidence of benefit of delaying cord clamping for at least 1 minute in term and preterm infants not requiring resuscitation. There is insufficient evidence to support or refute a recommendation to delay cord clamping in babies requiring resuscitation.

No recommendation.

- *General assessment:* It is done using pediatric assessment triangle (brief visual and auditory observation of child's overall condition to focus on A: appearance, B: work of breathing and C: circulation)
- *Primary assessment:* It is rapid evaluation of cardiopulmonary and neurologic function to include A: Airway, B: Breathing, C: Circulation, D: Disability and E: Exposure
- *Secondary assessment:* It is focused medical history using sample mnemonic S: Signs and symptoms, A: Allergies, M: Medications, P: Pastmedical history, L: Last meal, E: Events leading to current illness and thorough head to toe physical exam
- *Tertiary assessment:* It includes laboratory, radiographic, and other ancillary studies.

- Upper airway obstruction (e.g. croup)
- Lower airway obstruction (e.g. bronchiolitis, status asthmaticus)
- Lung parenchymal disease (e.g. bronchopneumonia)
- Disordered control of breathing (e.g. seizure, coma, muscle weakness)

Initial management aims to support airway, breathing, and circulation:

- *Airway:* Key steps in basic airway management include i) providing 100 percent inspired oxygen, ii) allowing the child to assume position of comfort or manually open airway, iii) Clearing airway (suction) or use of oropharyngeal airway or nasopharyngeal airway if consciousness impaired
- *Breathing:* One should assist ventilation manually in patients not responding to basic airway maneuvers and at the same time monitor oxygenation by pulse oximetry and ventilation by end-tidal CO₂ if available, and administer medications like salbutamol or epinephrine as needed. Children who cannot maintain their airway, oxygenation, or ventilatory requirements need an artificial airway, usually via endotracheal intubation or a laryngeal mask airway.

Respiratory Distress and Failure

Early detection and treatment of respiratory distress and failure result in improvement of overall outcome. There are many causes of acute respiratory compromise in children. The clinician should attempt to categorize the cause of respiratory distress or failure into one or more of the following:

- Circulation key interventions include monitoring heart rate and rhythm and establishing vascular access .

Shock

Early recognition and categorization of the type of shock is important to prioritize treatment options. Early management of shock may prevent the progression to cardiopulmonary failure. Shock results from the inadequate delivery of oxygen to the tissues relative to tissue metabolic demand, usually characterized by inadequate perfusion. Shock may occur with normal, increased, or decreased systolic blood pressure. Shock in children is usually related to low cardiac output, but some patients may have high cardiac output, such as with sepsis or severe anemia.

Severity of shock is usually classified by its effect on systolic blood pressure:

- Compensated shock occurs when compensatory mechanisms maintain a systolic blood pressure within a normal range.
- Hypotensive shock (or decompensated shock) occurs when compensatory mechanisms fail to maintain systolic blood pressure.

In children 1 to 10 years of age, hypotension is defined as:

- Systolic pressure (5th percentile) $<70 \text{ mmHg} + (\text{child's age in years} \times 2)$
- For infants 1 to 12 months of age, hypotension is defined by systolic pressure $<70 \text{ mmHg}$, and, in term infants 0 to 1 month of age, systolic pressure $<60 \text{ mmHg}$.¹² Systolic blood pressure $<90 \text{ mmHg}$ indicates hypotension in children over 10 years of age.

Shock Categorization

There are four major categories of shock based on pathophysiology.

- *Hypovolemic shock:* It is characterized by inadequate circulating blood volume like in diarrhea or burns
- *Distributive shock:* It is characterized by inappropriately distributed blood volume typically associated with decreased systemic vascular resistance like in septic shock, anaphylactic shock
- *Cardiogenic shock:* It refers to impairment of heart contractility like in congenital heart disease, myocarditis and cardiomyopathy
- *Obstructive shock:* Here the shock arises because of obstructed blood flow to the heart like in cardiac tamponade or tension pneumothorax

Any given patient may suffer from more than one type of shock. For example, a child in septic shock may develop hypovolemia during the prodrome phase, distributive shock during the early phase of sepsis, and cardiogenic shock later in the course.

Shock Management

The approach to undifferentiated shock in children requires careful attention to history and physical examination in order to arrive at the type of shock present. Goals of management are to improve oxygen delivery and to reduce oxygen consumption. Specific measures include increasing circulating volume, increasing cardiac contractility, improving distribution of cardiac output, and reducing oxygen demand. Depending on the severity and cause of shock, one or more of the following measures are needed to manage a child with shock.

- Administration of high concentration of oxygen and support of respirations to decrease the work of breathing
- Rapid intravenous administration of fluids (e.g., boluses of normal saline 20 mL/ kg up to three times or more as needed for persistent hypotension)
- Administration of vasoconstrictors and/ or inotropes in selected patients
- Reversal of identified obstructions and other adjunct methods including treatment of underlying infection, fever, pain and anxiety, and treatment of metabolic derangements (hypoglycemia, hypocalcemia, hyperkalemia, metabolic acidosis)

CARDIOPULMONARY FAILURE

Respiratory failure and hypotensive shock are the most common conditions foregoing cardiac arrest. The patient in cardiopulmonary failure will progress rapidly to cardiac arrest without aggressive intervention. The following physical findings often herald cardiopulmonary failure:

- *Airway:* Possible upper airway obstruction secondary to decreased level of consciousness or anatomic obstruction from foreign body or infection
- *Breathing:* Bradypnea, irregular, ineffective respiration, gasping
- *Circulation:* Bradycardia, capillary refill >5 seconds, weak central pulses, no peripheral pulses, hypotension, cool extremities, mottled/cyanotic skin
- *Disability:* Diminished level of consciousness.

The management of cardiopulmonary failure includes positive pressure ventilations with 100 percent oxygen, chest compressions for heart rate <60 beats per minute in patients with poor perfusion, and administration of intravenous fluids and medications tailored to treat the underlying cause are indicated.

Approach to Cardiac Arrhythmias

Arrhythmias are classified as bradyarrhythmias, tachyarrhythmias, and pulseless arrest. Assessment of arrhythmias depends on the age related heart rate and baseline rhythm as well as level of activity and clinical condition.^{5,6,8}

Bradyarrhythmias

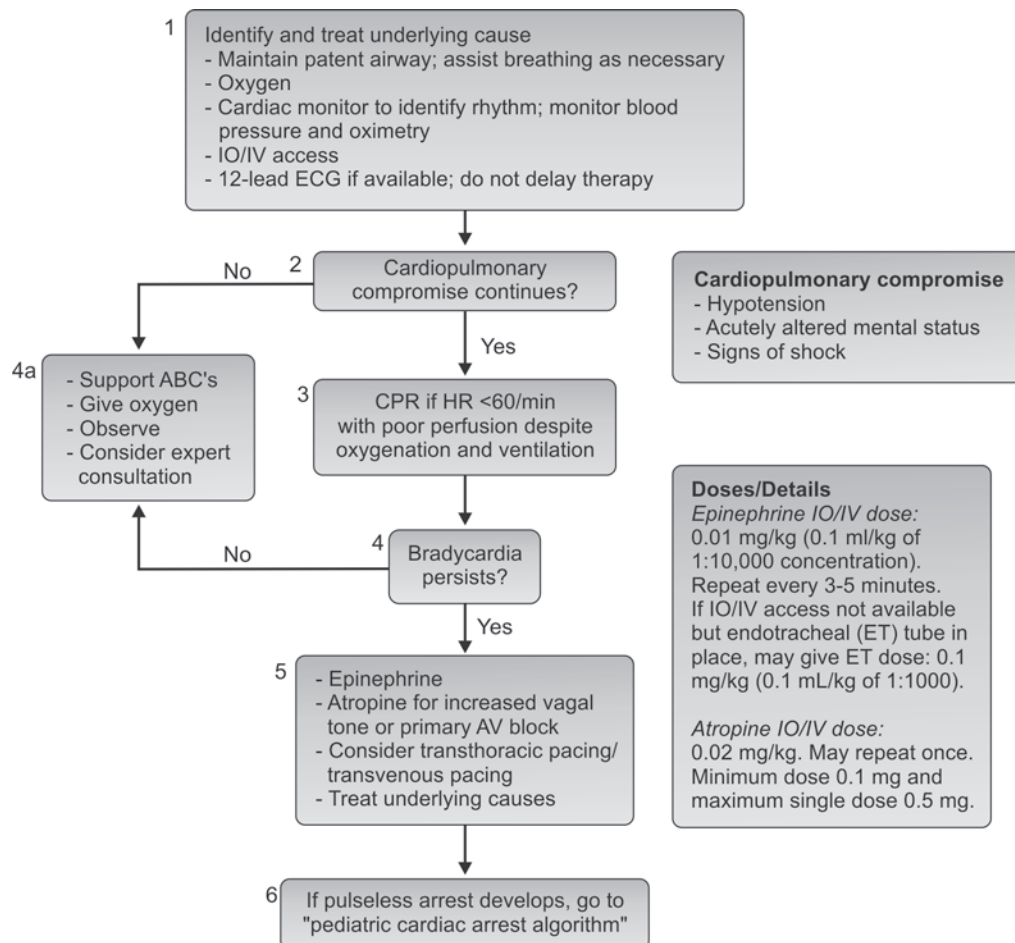

Bradycardia is defined as a heart rate that is slow compared with normal heart rates for the patient's age. Primary bradycardia results from congenital and acquired heart conditions that directly slow the spontaneous depolarization rate of the heart's pacemaker or slow conduction through the heart's conduction system. Secondary bradycardia is the result of conditions that alter the normal function of the heart, including hypoxia, acidosis, hypotension, hypothermia, and drug effects. Bradyarrhythmias are common pre-arrest rhythms in children and are often due to hypoxia. In emergency settings, the management of bradycardia focuses on reestablishing or optimizing oxygenation and ventilation, supporting circulation with chest compressions if needed, and using medications to increase heart rate and cardiac output (Flow chart 2). If these measures

fail, transcutaneous pacing can be attempted; however, the same factors that are producing refractory bradycardia (e.g. hypoxia, hypothermia, electrolyte disturbance, drug overdose) may prevent effective electrical capture.

Tachyarrhythmias

Tachyarrhythmias are fast abnormal rhythms originating in the atria or the ventricles. Relative tachycardia is a heart rate that is too fast for the child's age, level of activity, and clinical condition. In children, sinus tachycardia usually represents hypovolemia, fever, physiologic response to stress or fear, or drug effect (such as with beta agonists). Certain arrhythmias, such as supraventricular tachycardia and ventricular tachycardia, can lead to shock and cardiac arrest. Unstable rhythms lead to poor tissue perfusion with a fall in cardiac output, poor coronary artery perfusion,

Flow chart 2: Pediatric bradycardia algorithm (with a pulse and poor perfusion): 2010 PALS guidelines

PALS: pediatric advanced life support; CPR: cardiopulmonary resuscitation; IO: intraosseous; IV: intravenous; HR: heart rate; AV: atrioventricular; ABCs: air way, breathing, circulation. Source: Pediatric Advanced Life Support: 2010. American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. © 2010 American Heart Association, Inc.

and increased myocardial oxygen demand, which can all lead to cardiogenic shock. Management depends on differentiating between tachycardia with narrow QRS complex (sinus tachycardia, supraventricular tachycardia, atrial flutter) and wide QRS complex tachycardias (ventricular tachycardia, supraventricular tachycardia with aberrant intraventricular conduction).

Sinus tachycardia: Typical ECG findings in patients with sinus tachycardia include:

- Heart rate is usually <220/min in infants, <180/min in children, and exhibits beat to beat variability in rate
- P waves are present with normal appearance
- PR interval is constant and exhibits a normal duration for age
- R-R interval is variable
- QRS complex is narrow

Supraventricular tachycardia: Supraventricular tachycardia (SVT) can be defined as an abnormally rapid heart rhythm originating above the ventricles, often (but not always) with a narrow QRS complex; it conventionally excludes atrial flutter and atrial fibrillation. The two most common forms of SVT in children are atrioventricular re-entrant tachycardia (AVRT), including the Wolff-Parkinson-White (WPW) syndrome, and atrioventricular nodal reentrant tachycardia (AVNRT).

Typical ECG findings of SVT include:

- Heart rate that is usually >220/minute in infants, >180/min in children, and has no beat to beat variability
- P waves are absent or abnormal
- PR interval may not be present or short PR interval with ectopic atrial tachycardia
- R-R interval is usually constant
- QRS is usually narrow. Conduction delay along the ventricular system may lead to an appearance of wide complex tachycardia, known as SVT with aberrant conduction.

Ventricular tachycardia: Ventricular tachycardia (VT) originates from the ventricular myocardium or Purkinje cells below the bifurcation of the bundle of His. VT is associated with sudden cardiac death. As a result, patients who develop VT or at risk for developing VT must be identified, evaluated, and treated if necessary. VT may present with or without pulses. Causes of VT include underlying heart disease or cardiac surgery, prolonged QT syndrome, or myocarditis/cardiomyopathy. Other causes include hyperkalemia and toxic ingestions (e.g. tricyclic antidepressants).

Findings of ventricular tachycardia on ECG include:

- Ventricular rate is >120 beats per minute and regular
- P waves are often not identifiable, may have AV dissociation, or may have retrograde depolarization
- QRS is typically wide (>0.09 sec)
- T waves are often opposite in polarity from the QRS complex

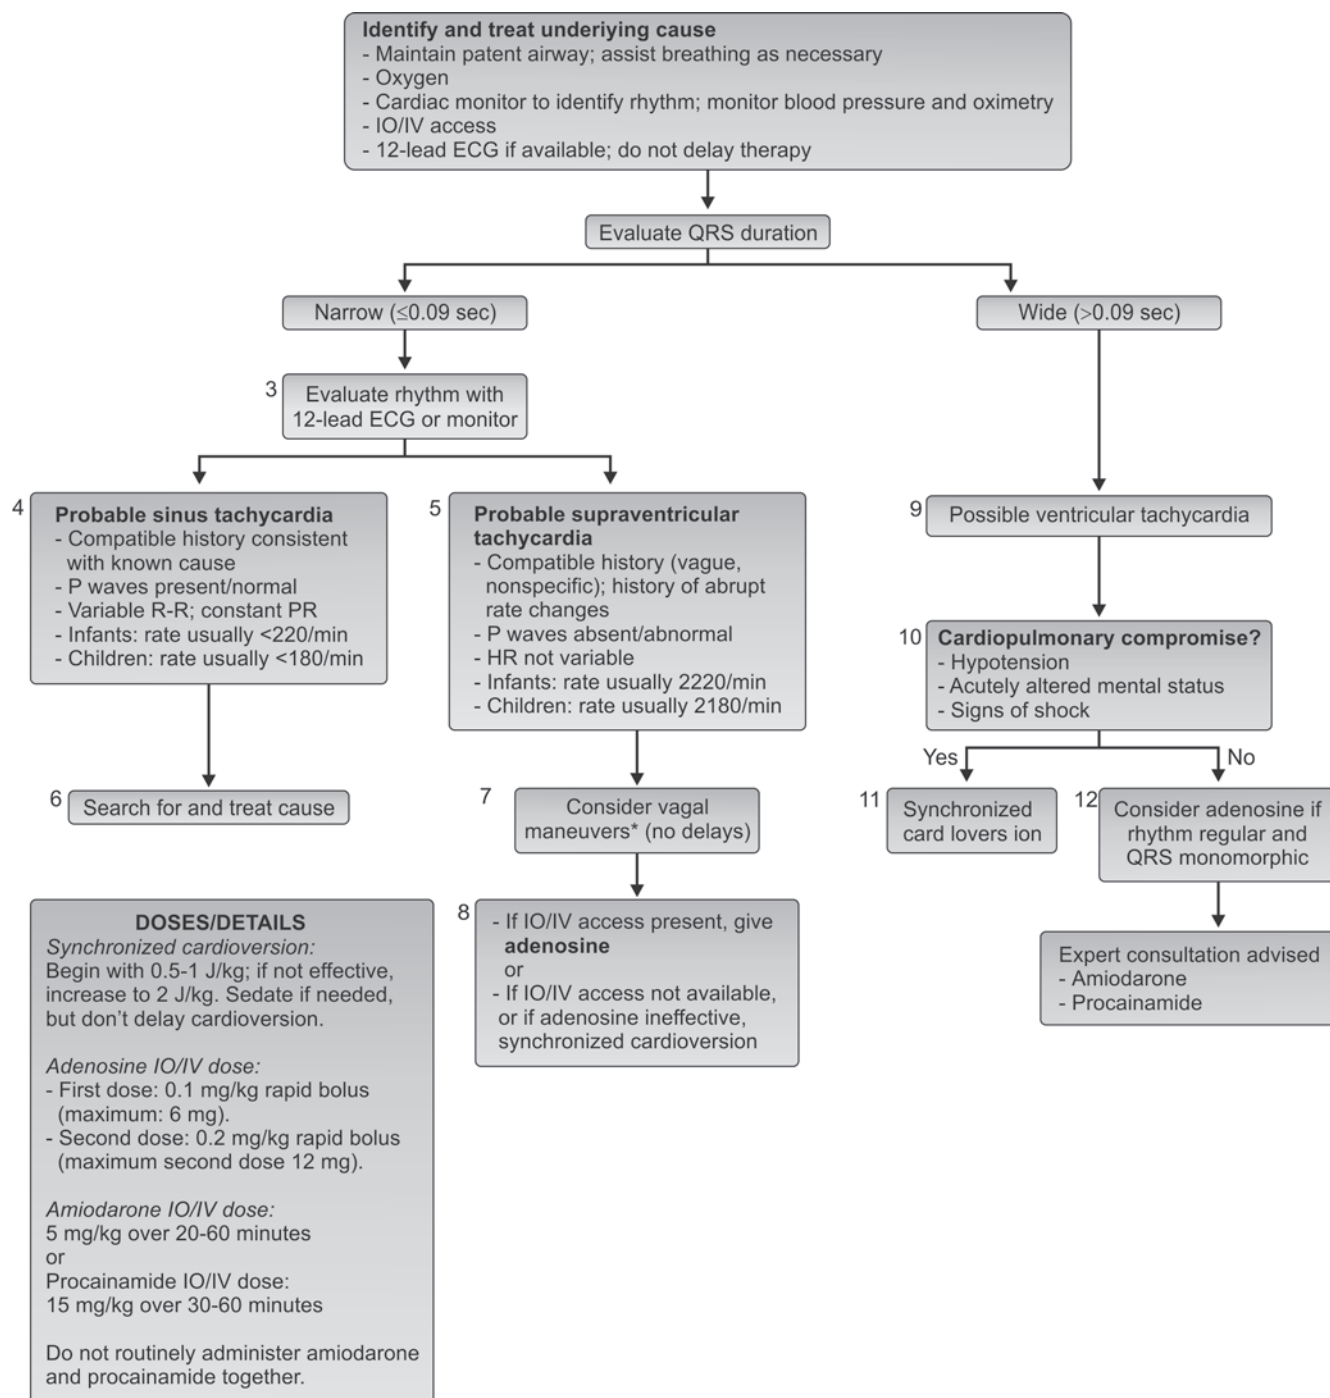

Tachyarrhythmia management: The management of sinus tachycardia focuses on treatment of the underlying physiologic derangement and is largely supportive. The management of tachyarrhythmia that are not sinus in origin is guided by the appearance of the QRS complex, and by the patient's status, whether compensated or uncompensated (Flow chart 3):

- Patients with either narrow or wide complex tachycardia who have significantly impaired consciousness and hypotensive shock should be treated with synchronized cardioversion
- Patients who are relatively stable may receive a trial of anti-arrhythmic therapy, based on whether the arrhythmia is believed to originate from above the AV node (narrow complex, e.g. adenosine; initial dose: 0.1 mg/kg) or below the AV node (wide complex, e.g. amiodarone 5 mg/kg).

Pulseless Arrest

Pulseless arrest refers to cessation of blood circulation caused by absent or ineffective cardiac mechanical activity. Most pediatric cardiac arrests are hypoxic/asphyxial arrests that result from a progression of respiratory distress, respiratory failure, or shock rather than from primary cardiac arrhythmias ("sudden cardiac arrest"). Thus, the presenting rhythm is typically asystole. The pulseless arrest can also be associated with pulseless electrical activity (PEA), ventricular fibrillation (VF), and pulseless ventricular tachycardia (VT). Children with pulseless arrest appear apneic or display a few agonal gasps. They have no palpable pulses, and are unresponsive. Overall survival from pediatric cardiac arrest is poor, and the incidence of neurologic deficits in survivors is high.

Out-of-hospital arrests in children six months to young adulthood often occur at or near home. The most common cause of death is from trauma, leading to respiratory compromise and/ or shock. Massive head injury and severe multiple systems trauma are common in non-survivors. Sudden infant death syndrome (SIDS) is a leading cause of death in infants <6 months. Sudden collapse due to VF/ pulseless VT occurs in up to 18 percent of all pediatric prehospital cardiac arrests, but is less commonly the presenting rhythm in younger children between the ages of one and eight years (7.6%).¹³ Predisposing conditions include hypertrophic cardiomyopathy, anomalous coronary artery (from the pulmonary artery), long QT syndrome, myocarditis, drug intoxication, and commotio cordis (i.e., sharp blow to chest). These patients may have intact survival if defibrillation is performed within minutes of arrest. For in-hospital cardiac arrest, shockable rhythms are present at some point during the resuscitation in 27 percent of children, with 10 percent having VF/ VT as the initial arrest rhythm. Survival is higher if VF or VT is the presenting arrhythmia (35% survival) versus "non- shockable" rhythms, such as asystole (11%).²

Flow chart 3: Pediatric tachycardia algorithm (with a pulse and poor perfusion): 2010 PALS guidelines

PALS: Pediatric advanced life support; IO: Intraosseous; IV: Intravenous; ECG: electrocardiogram.

* Vagal maneuvers: In infants or young children, place a plastic bag filled with ice and cold water over the face for 15 to 30 seconds or stimulate the rectum with a thermometer. In older children, encourage bearing down (Valsalva maneuver) for 15 to 20 seconds. Carotid massage and orbital pressure should not be performed in children. Source: Pediatric Advanced Life Support: 2010. American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. © 2010 American Heart Association, Inc.

- *Asystole*: Children with asystole have cardiac standstill with no discernible electrical activity.
- *Pulseless electrical activity (PEA)*: It consists of any organized electrical activity observed on ECG in a patient with no central palpable pulse. Reversible conditions which may underlie PEA includes H's (Hypovolemia, Hypoxia, Hydrogen ion (acidosis), Hypo-/hyperkalemia Hypoglycemia and Hypothermia) and T's (Toxins, Tamponade cardiac, Tension pneumothorax, Thrombosis-coronary or pulmonary and Trauma)
- *Ventricular fibrillation*: It is characterized by chaotic electrical activity with no organized rhythm and no coordinated contractions.
- *Pulseless VT*: It is a cardiac arrest of ventricular origin characterized by organized, wide QRS complexes. Torsades de pointes or polymorphic VT displays a QRS complex that changes in polarity and amplitude, appearing to rotate around the ECG isoelectric line (translation: "twisting of the points"). This arrhythmia may be associated with markedly prolonged QTc interval from congenital conditions, drug toxicity and electrolyte disturbances (e.g. hypomagnesemia). Ventricular tachycardia, including torsades de pointes, can deteriorate into ventricular fibrillation.

Management: The most important part of management for pulseless arrest is highly effective chest compressions (push hard, push fast, allow complete chest recoil, and minimize interruptions) by a trained person. The compressions should be interrupted only for ventilation, rhythm check, and shock delivery. Once basic cardiopulmonary resuscitation is established, treatment of pulseless arrest requires rapid assessment of rhythm, performance of defibrillation as indicated, and pharmacotherapy aimed at increasing coronary artery circulation and restoration of organized cardiac conduction (Flow chart 4).

Vascular Access

It is a critical step in pediatric resuscitation. During pulseless arrest, intraosseous cannulation and peripheral venous access should be pursued simultaneously. Resuscitation medications given through a peripheral IV should be followed with a 5 mL flush of normal saline to move the drug from the peripheral to the central circulation. Many pediatricians prefer intraosseous cannulation as the initial route of vascular access, especially in young infants with pulseless arrest. Attempts at peripheral and central venous access in the head, neck, and chest should not interrupt chest compressions. Central lines are more secure than peripheral access and provide more rapid onset and higher peak concentration of medications but are not required during initial resuscitation attempts.

Endotracheal Drug Administration

Although lipid soluble drugs, such as lidocaine, epinephrine, atropine, and naloxone ("LEAN"), may be

administered via endotracheal tube (ETT), the intravascular route is always preferred. Optimal drug dosing via endotracheal tube is unknown, with unpredictable drug absorption leading to lower blood levels when compared with the same dose given intravascularly. While using ETT route for drug administration, one should increase the epinephrine dose tenfold and the dose of other medications (atropine, lidocaine, naloxone) two- to threefold. It is important to hold compressions during ETT administration and follow a drug administration with 3 to 5 mL of normal saline and provide five positive pressure ventilations after instilling the drug.

Defibrillation

Defibrillation does not restart the heart; the shock "stuns" the heart by depolarizing all of the myocardial cells, hopefully terminating VF and allowing the heart's natural pacemaker cells to resume an organized rhythm. After delivering a shock, the caregivers should perform five cycles of CPR before checking the rhythm. CPR may be discontinued if a perfusing rhythm has been established. Biphasic defibrillators have a high first shock efficacy rate for ventricular fibrillation (VF) of short duration in adults. This procedure eliminates VF but may not lead to a perfusing rhythm (often the patient will be in asystole or PEA) or myocardial ischemia prevents proper cardiac contractility. After delivering the shock, chest compressions should resume immediately for five cycles. Cardiopulmonary resuscitation is required to maintain blood flow to the heart, coronary circulation, and brain until effective cardiac contractility resumes.

Although manual defibrillators or automated external defibrillators with pediatric attenuating devices are preferred for use in infants and children, automated external defibrillators without pediatric attenuating devices may be used if they are the only option available.

Pharmacologic Therapy

Epinephrine is the most commonly used medication in children with pulseless arrest. It is classified as a catecholamine, vasopressor, and inotrope. For pulseless arrest, the IV/IO dosing is 0.01 mg/kg (0.1 mL/kg of the 1:10,000 concentrations given every three to five minutes; maximum single dose: 1 mg (10 mL)). High dose epinephrine is no longer recommended with the exception of endotracheal dosing. When epinephrine is administered via ET tube, use 0.1 mg/kg (0.1 mL/kg of the 1:1000 concentration by endotracheal tube every three to five minutes). The IV/IO route is always preferred. A brief summary of the resuscitation drugs is given in Table 3.

Early Postresuscitation Management

The early postresuscitation period involves the time soon after return of spontaneous circulation or recovery from

circulatory or respiratory failure. During this time, the clinician must continue to treat the underlying cause for the life threatening event and monitor for common respiratory or circulatory problems that may cause secondary morbidity or death.⁸

Oxygen administration: Once return of spontaneous circulation has been achieved, the clinician should titrate inspired oxygen to maintain arterial oxyhemoglobin saturation ≥ 94 –99 percent while avoiding hyperoxemia.

Intubated patients: All intubated children require continued assessment to ensure proper endotracheal tube positioning, continuous monitoring of oxygenation (pulse oximetry), and ongoing monitoring of ventilation (e.g., continuous end-tidal CO₂ monitoring, if available, and/or intermittent blood gas assessment). Insertion of a gastric tube helps to reduce gastric distension. The causes of sudden decompensation in a child who has been successfully intubated with an artificial airway are described by the mnemonic “DOPE”:

- D: Dislodged or displaced endotracheal tube (right mainstem or esophageal location)
- O: Obstructed endotracheal tube (e.g. mucous plug, kinked endotracheal tube)
- P: Pneumothorax
- E: Equipment failure (e.g. ventilator malfunction, oxygen disconnected or off)

Recurrent shock: After fluid resuscitation in a child, circulatory instability may recur as the result of ongoing fluid loss, decreased cardiac function, and/or harmful alterations in systemic vascular resistance. Goal-directed therapy emphasizes the need to assess clinical findings of perfusion (e.g. capillary refill, urine output), measure central venous pressure, and measure central venous oxygen saturation, to determine the best course of action. If the child is not being treated in a center with pediatric emergency and critical care expertise, the child should be stabilized and rapidly transferred for definitive care at a regional pediatric center. Critically ill or injured children typically

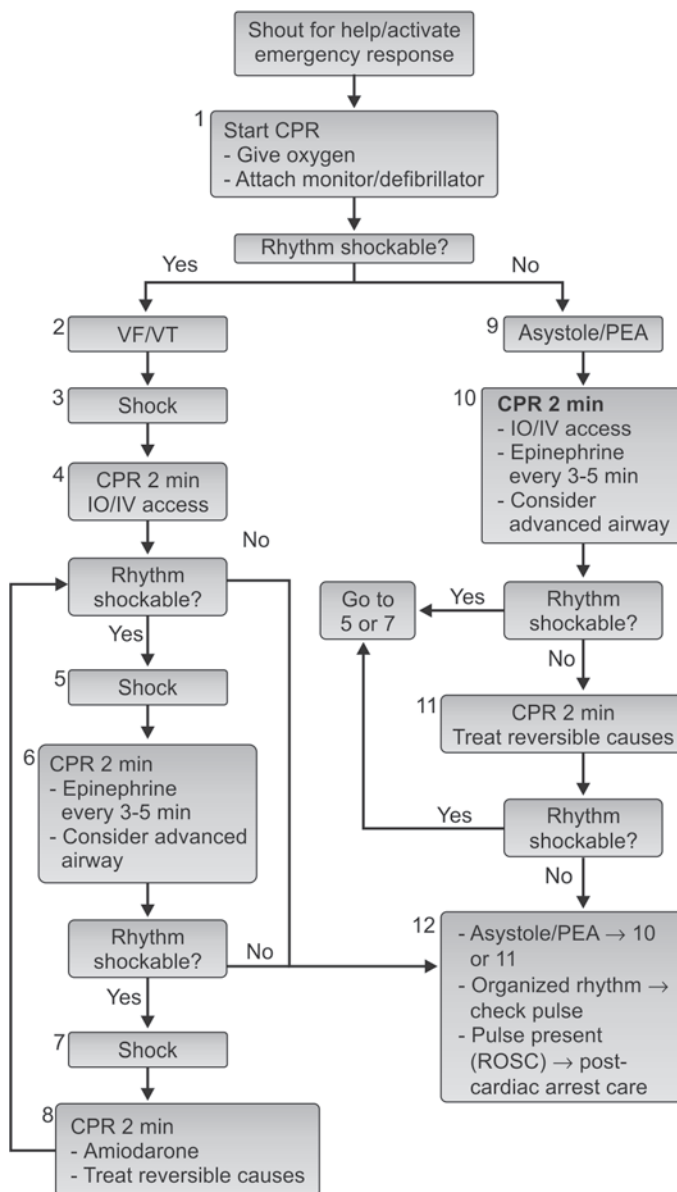

Table 3: Pediatric Resuscitation Pharmacology

Medication	Dose	Remarks
Adenosine	0.1 mg/kg (maximum 6 mg) Second dose: 0.2 mg/kg (maximum 12 mg)	Monitor ECG Rapid IV/IO bolus with flush
Amiodarone	5 mg/kg IV/IO; may repeat twice up to 15 mg/kg Maximum single dose 300 mg	Monitor ECG and blood pressure; adjust administration rate to urgency (IV push during cardiac arrest, more slowly—over 20–60 minutes with perfusing rhythm). Expert consultation strongly recommended prior to use when patient has a perfusing rhythm. Use caution when administering with other drugs that prolong QT (obtain expert consultation)
Atropine	0.02 mg/kg IV/IO 0.04–0.06 mg/kg ET* Repeat once if needed Minimum dose: 0.1 mg Maximum single dose: 0.5 mg	Higher doses may be used with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg) Maximum single dose 2 g	Administer slowly
Epinephrine	0.01 mg/kg (0.1 mL/kg 1:10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1:1000) ET* Maximum dose 1 mg IV/IO; 2.5 mg ET	May repeat every 3–5 minutes
Glucose	0.5–1 g/kg IV/IO	Newborn: 5–10 mL/kg D ₁₀ W Infants and Children: 2–4 mL/kg D ₂₅ W Adolescents: 1–2 mL/kg D ₅₀ W
Lidocaine	Bolus: 1 mg/kg IV/IO Infusion: 20–50 mcg/kg/minute	
Magnesium sulfate	25–50 mg/kg IV/IO over 10–20 minutes, faster in torsades de pointes Maximum dose 2 g	
Naloxone	Full Reversal: <5 y or ≤ 20 kg: 0.1 mg/kg IV/IO/ET* ≥ 5 y or >20 kg: 2 mg IV/IO/ET*	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1–5 mcg/kg titrate to effect)
Procainamide	15 mg/kg IV/IO Adult Dose: 20 mg/min IV infusion to total maximum dose of 17 mg/kg	Monitor ECG and blood pressure; Give slowly—over 30–60 minutes. Use caution when administering with other drugs that prolong QT (obtain expert consultation)
Sodium bicarbonate	1 mEq/kg per dose IV/IO slowly	After adequate ventilation

• IV indicates intravenous; IO, intraosseous; and ET, via endotracheal tube.

• * Flush with 5 mL of normal saline and follow with 5 ventilations

Flow chart 4: Pediatric Cardiac Arrest Algorithm: 2010 PALS Guidelines

**Doses/details****CPR quality**

- Push hard ($\geq 1/3$ of anterior-posterior diameter of chest) and fast (at least 100/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes
- If no advanced airway, 15:2 compression-ventilation ratio. If advanced airway, 8-10 breaths with continuous chest compressions

Shock energy for defibrillation

First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥ 4 J/kg, maximum 10 J/kg or adult dose.

Drug therapy

- Epinephrine IO/IV dose: 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes. If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration).

- Amiodarone IO/IV dose:

- 5 mg/kg bolus during cardiac arrest. May repeat up to 2 times for refractory VF/pulseless VT.

Advanced airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place give 1 breath every 6-8 seconds (8-10 breaths per minute)

Return of spontaneous circulation (ROSC)

- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible causes

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypoglycemia
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

PALS: Pediatric advanced life support; VF: Ventricular fibrillation; VT: Ventricular tachycardia; PEA: Pulseless electrical activity; IO: Intraosseous; IV: Intravenous; CPR: Cardiopulmonary resuscitation; ROSC: Return of spontaneous circulation. benefit from transport by a team with pediatric expertise and advanced pediatric treatment capability, although in some isolated cases (e.g. expanding epidural hematoma) more rapid transport by an immediately available non-pediatric team may be advantageous.

Prior to transfer the physician responsible for the child's care at the transferring hospital should speak directly to the physician who will be taking charge of the patient at the receiving hospital. All documentation of care (e.g. medical chart, medication administration

record, laboratory results, copies of ancillary studies (radiographs, ECGs)) should be sent with the patient.

Family Presence During Resuscitation

Observational studies indicate that caretakers should be given the option of being present during the in-hospital resuscitation of their child.⁸ Most parents want the opportunity to remain with their child during resuscitation and believe it is their right. Caretakers present during the resuscitation of a family member frequently reported that their presence during the resuscitation was beneficial to the patient. Two-thirds of caretakers present during the resuscitation of a child who died reported that their presence helped with their adjustment to the death and the grieving process. Studies of hospital personnel suggest that the presence of a family member, in most instances, was not stressful to staff and did not negatively impact staff performance. When family members are present during a pediatric resuscitation, a staff member with clinical knowledge, empathy, and strong interpersonal skills should be present with them to provide support and answer questions. In the rare instance that family presence is disruptive to team resuscitation efforts, the family members should be respectfully asked to leave.¹⁴⁻¹⁶

Clinically Useful Classification and an Approach to Acyanotic Congenital Heart Disease

Manvinder Singh Sachdev

INTRODUCTION

Congenital heart defects (CHD) occur due to structural malformation of the heart or great vessels during intrauterine development of the fetus. Although the defects are present from birth the age of presentation can vary from newborn period to adulthood.¹ According to studies from different parts of the world the incidence of congenital heart defects is 7 to 8 per 1000 live-born infants and they cause 3 percent of all infant deaths. The incidence of CHD has remained almost the same over the past few years. About 33 to 50 percent of these defects are critical. A critical CHD can be defined as a congenital heart disease which requires surgery or catheter intervention in the first year of life.² Early detection and appropriate management can significantly improve the morbidity and mortality and the outcome of congenital heart defects.³

CLASSIFICATION OF CONGENITAL HEART DISEASE

Congenital heart defects may be classified into acyanotic and cyanotic heart disease based on the type of defect and presence of cyanosis.¹

Acyanotic Lesions

Acyanotic heart defects can be further categorized as lesions which either increase the volume load of the heart, i.e. those with increased pulmonary blood flow or increase the pressure load on the heart (obstructive) (Table 1). Heart defects which cause left-to-right shunt lesions increase the volume load of the heart whereas increased pressure load is caused due to defects which cause ventricular outflow obstruction or narrowing of any of the great vessels (aorta or pulmonary artery).⁴ In acyanotic cardiac lesions pulmonary blood flow is normally adequate or even excessive, but the systemic blood flow is compromised.

Blood is oxygenated appropriately in the lungs, but it is not delivered efficiently to the tissues.⁴

Cyanotic Lesions

In cyanotic congenital heart defects with reduced pulmonary blood flow, the blood flow to the systemic vasculature is well maintained, but blood flow to the pulmonary vasculature is compromised as the systemic venous blood bypasses the pulmonary circulation and enters the left side of the heart (right to left shunt). Hence,

Table 1: Classification of congenital heart anomalies

Cyanotic heart diseases	
<i>Increased pulmonary blood flow</i>	<i>Examples</i>
	<ul style="list-style-type: none">• Transposition of the great arteries• Total anomalous pulmonary venous return• Tricuspid atresia, without PS• Persistent truncus arteriosus
<i>Decreased pulmonary blood flow</i>	<i>Examples</i>
	<ul style="list-style-type: none">• Tetralogy of Fallot• Pulmonary atresia• Tricuspid atresia, VSD, pulmonary stenosis• DORV, VSD, PS• TGA VSD PS
Acyanotic	
<i>Increased pulmonary blood flow</i>	<i>Examples</i>
	<ul style="list-style-type: none">• Ventricular septal defect• Atrial septal defect• Patent ductus arteriosus• Atrioventricular septal defect
<i>Obstructive</i>	<i>Examples</i>
	<ul style="list-style-type: none">• Pulmonary stenosis• Aortic stenosis• Aortic coarctation

even though blood is delivered to the tissues efficiently, systemic arterial desaturation (cyanosis) occurs as the blood is not adequately oxygenated.⁴ The other type of lesions in cyanotic congenital heart disease is those with increased pulmonary blood flow where cyanosis occurs as a result of mixing of the oxygenated and deoxygenated blood. Cyanosis caused due to intrapulmonary right to left shunting and pulmonary venous desaturation due to congestive heart failure are not included in cyanotic CHD.¹

WHY IS CLASSIFICATION NECESSARY

The physiologic presentations and age of presentation of the various congenital heart anomalies (cyanotic and acyanotic heart diseases) are variable. Congenital cardiac lesions may present as asymptomatic heart murmur, cyanosis (often without a murmur), or catastrophic heart failure and shock.⁵ A good understanding and knowledge about the range of abnormalities and possible presentations of the various cyanotic and acyanotic heart diseases are important for accurate diagnosis and improving outcome of congenital heart anomalies. According to studies timely recognition of hemodynamically significant congenital heart disease can improve outcomes hence it is important to have strategies that can help in timely diagnosis and appropriate treatment.^{5,6}

APPROACH TO ACYANOTIC CONGENITAL HEART DISEASE

A systematic approach while treating a child with possibly acyanotic congenital heart disease is important as it helps to arrive at the provisional diagnosis of the lesion and initiate management accordingly in this subgroup of patients. An effective diagnostic strategy while dealing with patients with possibly acyanotic congenital heart disease, at presentation can expedite diagnosis and management and improve overall prognosis.

The following step-wise approach is usually needed:

Differentiating Cyanotics and Acyanotics

The first step in approaching any patient with congenital heart disease is differentiating cyanotics from acyanotic patients. Cyanosis is caused due to presence of desaturated blood in the capillary beds as deoxygenated hemoglobin is blue. When an infant or child presents with cyanosis it means that at least 3 to 5 mg/dl of deoxyhemoglobin in the blood is present in blood. In presence of any of the following findings the patient is classified as cyanotic congenital heart disease:

- Presence of central cyanosis
- Saturation by pulse oximeter of <94 percent.

All other patients are labeled as acyanotic congenital heart disease. As cyanosis becomes evident to naked eye only when the saturation falls below 85 percent, pulse oximeter is a very important tool in differentiating cyanotic congenital heart disease from acyanotic congenital heart disease.⁷

Identify Patients with Increased Pulmonary Blood Flow

The left-to-right shunt lesions ventricular septal defects, atrial septal defects, patent ductus arteriosus, and endocardial cushion defects comprise about 50 percent of all congenital heart disease. In these lesions blood is shunted from the systemic system into the pulmonary system resulting in increased pulmonary blood flow. The high pulmonary vascular resistance in the neonate period limits the amount of shunt but with decrease in pulmonary vascular resistance after the first few weeks of life increases the pulmonary blood flow and pressures. Clinical manifestation and severity of presentation is directly proportional to the degree of pulmonary vascular blood flow. Higher blood flow causes chamber enlargement and signs of congestive heart failure.⁸ Increase pulmonary blood flow is suspected in presence of one or more of the following features on physical examination:

- Recurrent lower respiratory tract infection (LRTI)
- Feeding difficulty
- Excessive sweating
- Hyperdynamic precordium
- Failure to gain adequate weight or failure to thrive
- Presence of tachypnea, tachycardia and retractions.

Objective assessment of pulmonary blood flow can be made from a chest X-ray (Fig. 1). Features of increased PBF on CXR:

- Cardiomegaly
- Presence of >4 end on vessels in the middle 1/3rd of the lung field
- If >6 vessels can be traced to the lateral 1/3rd.

Small left to right shunts may not show the presence of either the clinical parameters or CXR findings of increased pulmonary blood flow.

Fig. 1: CXR showing cardiomegaly with increased pulmonary blood flow

Presenting Features and Age of Presentation

Clinical presentation and age of presentation is different for the various acyanotic congenital heart diseases.

Ventricular Septal Defect (VSD)

Patients with large or a moderate sized VSD usually present with history of recurrent LRTI, feeding difficulty and failure to gain weight. These children usually present in early infancy and are quite symptomatic.

Atrial Septal Defect (ASD)

These patients usually present beyond infancy and are usually picked up as a result of a gracile built. They do not present with features of increased blood flow. <10 Percent of patients with ASD present with congestive heart failure.

Patent Ductus Arteriosus (PDA)

Presenting features and age of presentation is almost same as that of patient with VSD.

Obstructive Lesions

These patients are usually asymptomatic except in presence of critical lesions. Symptoms include dyspnea on exertion, chest pain and palpitation.

Clinical Examination

Pulse and Blood Pressure

Examination of pulse and measurement of blood pressure (BP) in all the four limbs helps to diagnose patient with coarctation of the aorta.

- In coarctation lower limb pulses may be feeble or absent. Four limb BP measurements may show evidence of upper limb hypertension.
- Bounding pulses may be present in a child with PDA.

Precordial Activity

- In a large VSD or PDA precordium is usually hyperdynamic
- Hyperkinetic LV apex is usually observed in patients with moderate to large VSD and PDA
- Forceful LV type apex is noted in left side obstructive lesions like AS/coarctation of aorta
- RV heave is a common finding in patient with moderate to severe pulmonary stenosis.

Second Heart Sound

- Accurate auscultation of 2nd heart sound helps to arrive at a workable diagnosis of congenital heart disease
- Wide and fixed split S2 is usually present in patient with ASD

- Closely split S2 with loud P2 is heard in presence of large VSD
- Wide and variable split S2 with normal intensity of P2 is usually found in cases of moderate VSD
- Second heart sound may be normal in patients with small VSD, mild to moderate PS and in patients with congenital aortic stenosis of any severity
- Wide and variable split second heart sound with soft pulmonary component is found in patients with moderate to severe pulmonary stenosis.

Murmur

Pansystolic murmur: Presence of pansystolic murmur in patients of acyanotic congenital heart disease indicates:

- *Moderate VSD:* Murmur at left parasternal area.
- *Tricuspid regurgitation:* Murmur heard at left parasternal area increasing on inspiration
- *Mitral regurgitation:* Murmur best heard at the apex and radiating to the axilla.

Systolic ejection murmur:

- *Aortic stenosis:* Systolic ejection murmur of AS is best heard in the right and left upper parasternal area and radiating to the carotids.
- *Pulmonary stenosis:* Murmur is best heard in the pulmonary area and radiates to the lung fields. The murmur is usually of harsh quality.
- *Large VSD:* Systolic ejection murmur of a large VSD is best heard in left upper parasternal area and is usually of a short duration. The intensity of the murmur is usually grade 2.

Continuous murmur: Continuous murmur heard in the left infraclavicular area is usually due to a small to moderate patent ductus arteriosus.

Chest X-ray (CXR)

ASD (Fig. 2)

- Cardiomegaly
- Right atrial enlargement
- Dilated main pulmonary artery
- Increased pulmonary vascular markings.

VSD (Fig. 3)

- Cardiomegaly
- Left ventricular enlargement
- Increased pulmonary vascular markings.

PDA (Fig. 4)

- Cardiomegaly
- Left ventricular enlargement
- Increased pulmonary vascular markings
- Prominent aorta.

Fig. 2: CXR showing cardiomegaly with right atrial enlargement with increased pulmonary blood flow

Fig. 3: CXR shows cardiomegaly with left ventricular enlargement with increased pulmonary blood flow

Fig. 4: CXR showing mild cardiac enlargement with left ventricular type apex with prominence of aortic Knuckle and normal pulmonary blood flow (CXR of small PDA)

Fig. 5: CXR showing normal cardiac silhouette with normal pulmonary vascular markings with prominent main pulmonary artery (poststenotic dilatation) in a case of severe valvular pulmonary stenosis

CXR of PS (Fig. 5)

- Normal size heart
- Dilated main pulmonary artery (MPA) and left pulmonary artery (LPA)
- Normal pulmonary vascular markings.

CXR of AV Canal Defect (Fig. 6)

- Cardiomegaly
- Left atrial and left ventricular enlargement
- Increased pulmonary blood flow.

ECG**ASD (Fig. 7)**

- Right axis deviation
- Right atrial enlargement
- Rsr' in V1

VSD/PDA (Fig. 8)

- Normal axis, right axis deviation seen in presence of pulmonary hypertension
- LVH (volume overload type)
- Biventricular hypertrophy seen in patients with Large VSD.

AV Canal Defect (Fig. 9)

- Superior axis
- Biventricular hypertrophy.

AS/COA (Fig. 10)

- Normal or left axis
- Left ventricular hypertrophy.

PS (Fig. 11)

- Right axis deviation
- Right ventricular hypertrophy.

Fig. 7: ECG of a child with secundum ASD showing RSR' pattern in lead V1

Fig. 8: ECG of a child with moderate ventricular septal defect showing normal axis with evidence of left ventricular volume overload

Fig. 9: ECG of a patient with complete AV canal defect showing northwest axis with right ventricular hypertrophy

Fig. 10: ECG of a patient with severe coarctation of aorta showing normal axis with left ventricular hypertrophy

Fig. 11: ECG showing right axis deviation with monophasic R wave in V1 suggestive of right ventricular hypertrophy

Fig. 12: ECG of a child with anomalous origin of the left coronary artery from pulmonary artery showing prominent q waves with lead I and aVL

ALCAPA (Fig. 12)

- Q in lead I and aVL.

CONCLUSION

To summarize it is very essential to classify congenital heart disease as this classification forms the basis of approach to these patients. Clinical approach supplemented with chest X-ray and ECG can help to arrive at a working diagnosis of the lesions. This can assist to initiate management in these patients before they are referred for further evaluation and management.

Cyanotic Congenital Heart Disease: A Diagnostic Approach

Neeraj Agarwal

INTRODUCTION TO CYANOSIS

Congenital heart defects are classified into two groups namely acyanotic congenital heart disease and cyanotic congenital heart disease (CCHD).¹ Cyanosis (Greek word meaning dark blue) can be central or peripheral, where central cyanosis is characterized by blue discoloration of nails and mucous membranes. It must be remembered that mild degree of desaturation may not be visible to naked eyes and can only be picked up by pulse oximetry.

Cyanosis is a serious sign (Table 1) and needs to be picked up as early as possible. There are different confounding factors (Table 2) which can mask the diagnosis or may lead to erroneous diagnosis of cyanosis. Naked eyes

Table 1: Principal causes of cyanosis

- *Peripheral cyanosis*
Cold, hypovolemia, low cardiac output, and autonomic vasomotor instability in newborn
- *Central cyanosis*
 - Respiratory disorders
Respiratory distress syndrome (hyaline membrane disease), pneumonia, bronchiolitis, asthma, pneumothorax, airway obstruction and bronchopulmonary dysplasia, pulmonary malformations, cystic fibrosis and various other congenital lesions in the newborn compromising the airways (e.g. diaphragmatic hernia, tracheo-oesophageal fistula, Choanal atresia and others).
 - Cardiovascular disorders
 1. Congenital heart disease with decreased pulmonary blood flow.
 2. Congenital heart disease with normal or increased pulmonary blood flow.
 3. Persistent pulmonary artery hypertension of the newborn.
 4. Pulmonary vascular disease (Eisenmenger physiology).
 5. Pulmonary arteriovenous malformation.
 - Neurological disorders including central apnea/drug induced apnoea and respiratory neuromuscular dysfunction like spinal muscular atrophy.
 - Abnormal hemoglobin: Methemoglobinemia

Table 2: Difficulty in diagnosis of cyanosis

Over diagnosis of CCHD

- Peripheral cyanosis
- Respiratory disease mimicking cyanotic heart disease
- Pulmonary congestion due to left to right shunts
- Cold extremities or shock with falsely low readings

Missed diagnosis of CCHD

- Mild cyanosis (frequently CCHD with high pulmonary flow)
- Anemia (at least 3 gm % of desaturated hemoglobin needed to manifest as cyanosis)
- Dark skin (naked eyes may miss cyanosis)

can usually pick up the cyanosis when saturation is less than 85 percent with a hemoglobin level of 12 to 13 gm percent. But there are various factors which will determine the visibility of cyanosis in a particular subject. Cyanosis is dependent on absolute concentration of deoxygenated hemoglobin (Hb) and not on the ratio of deoxygenated to oxygenated hemoglobin. Cyanosis will be visible to eyes if absolute deoxygenated hemoglobin is at least 3 gm percent in arterial blood (approximate equivalent of 5 gm percent in capillary blood). So if patient is anemic where total Hb level is low, the visibility of cyanosis will also be less or in other words, amount of desaturation has to be less to be visible to naked eyes in an anemic patient compared to a patient with normal Hb. Similarly, polycythemia patient may exhibit visible cyanosis even at 90 percent saturations (provided total deoxygenated Hb level is at least 3 gm%).

PERIPHERAL CYANOSIS

When peripheral vasoconstriction results in decreased peripheral perfusion, more oxygen is extracted from peripheral blood. Decrease in oxygen content of venous blood produces bluish discoloration. Patients with peripheral cyanosis have normal systemic arterial oxygen saturation.

Causes of peripheral cyanosis include vasomotor instability as seen in neonates, vasoconstriction caused by exposure to cold or hypovolemia, elevated venous pressure as in congestive heart failure (CHF), polycythemia, and low cardiac output. Polycythemia leads to increase in blood viscosity which impairs capillary blood flow producing excessive amount of reduced Hb. The increased extraction of oxygen results from sluggish movement of blood through the capillary circulation. To obviate the influence of cold temperature, infants should be examined for assessment of cyanosis while quiet in a neutral thermal environment. Although peripheral cyanosis is seen in conditions in which the infant is exposed to a cold environment, it could also be the presenting sign of serious conditions such as sepsis, hypoglycemia, or low cardiac output; hence peripheral cyanosis should not be ignored unless other conditions have been ruled out.

DIFFERENTIAL CYANOSIS

In this scenario, lower part of body is cyanotic and upper part of body is pink. This is seen in conditions in which there is right to left shunt from the pulmonary artery to the descending aorta through the patent ductus arteriosus (PDA). Any condition that gives rise to right-to-left shunt through the PDA is likely to give rise to differential cyanosis. Common examples include interrupted aortic arch with PDA and persistent pulmonary hypertension of newborn (PPHN). In reverse differential cyanosis, the upper part of the body remains cyanotic while the lower part of the body remains pink. Examples include transposition of the great arteries (TGA) with pulmonary hypertension and shunt through PDA, and also TGA with left ventricular outflow obstruction.

CLASSIFICATION OF CYANOTIC CONGENITAL HEART DISEASE (CCHD)

In cyanotic congenital heart disease, deoxygenated blood bypasses the pulmonary circulation and enters into the systemic circulation causing systemic deoxygenation. That means there should be a right to left shunt either at atrial level, ventricular level or great arteries level to cause cyanosis. CCHD does not include pulmonary right to left shunt (e.g. pulmonary arteriovenous malformations) and other noncardiac causes of cyanosis. Figure 1 illustrates an example of noncardiac cause of cyanosis.

There is an endless list for cyanotic congenital heart defects with various combinations and thus various classifications. Physiology is a practical classification system because physiology is what is dealt with clinically and CCHD patients can be grouped physiologically mainly into two groups—CCHD with low pulmonary blood flow, CCHD with high pulmonary blood flow.²⁻⁴ Admixture lesions are also a group in the classification system where cyanosis

Fig. 1: This newborn presented with respiratory distress and desaturation at birth. Chest X-ray showed left diaphragmatic hernia with mediastinal shift

results from obligatory mixing of desaturated blood with oxygenated blood.⁵ This can occur at venous level {(total anomalous pulmonary venous connection (TAPVC))}, atrial level (common atrium), ventricular level (single ventricle) or great arterial level (Truncus arteriosus) or TGA where partial mixing can occur at the level of atrial septal defect (ASD), ventricular septal defect (VSD) or PDA.

Although some combinations may have a balanced physiology and normal pulmonary blood flow for some time, they usually end up in either of these two subgroups. For example, a case of VSD and moderate pulmonary stenosis may be balanced enough to be asymptomatic or mildly cyanotic for a long time and as the severity of pulmonary stenosis increases over time, pulmonary blood flow will decrease and child will become more cyanotic. Similarly, a case of high pulmonary blood flow if left unoperated and pulmonary vascular resistance increases, then Eisenmenger physiology will develop where pulmonary blood flow is low.

There are few other groups in this classification system that cover lesions which are not commonly encountered. One of them is cyanotic heart disease without PS but normal pulmonary blood flow like SVC entering the left atrium. Pulmonary AVM is not a CCHD but this also presents with cyanosis and normal pulmonary blood flow. The other notable group is neonates presenting with features of pulmonary venous congestion like obstructed TAPVC/hypoplastic left heart syndrome (HLHS) with restrictive PFO (these lesions are separately covered in neonatal cardiac chapters).

Table 3: Cyanotic congenital heart defects—5 Ts to remember

Tetralogy of Fallot (TOF)
Tricuspid valve abnormalities—tricuspid atresia, tricuspid stenosis, tricuspid valve displacement (Ebstein anomaly and other Ebstein like malformations)
Truncus arteriosus
Total anomalous pulmonary venous connection
Transposition of great arteries

Famous 5T's can be remembered as the most commonly encountered cyanotic congenital heart defects. (Table 3)

ASSESSMENT OF PULMONARY BLOOD FLOW (QP)

As already described, cyanotic congenital heart disease is practically classified into two physiological groups based on pulmonary blood flow. The next critical question is how to assess pulmonary blood flow (Qp) in various clinical scenarios. There are few signs and symptoms which can help us in deciding the pulmonary blood flow and objective assessment of pulmonary blood flow can be done accurately with the help of Chest X-ray (CXR).^{3,4}

The features of high pulmonary blood flow are recurrent chest infections, failure to thrive, excessive sweating on feeding/activity, feeding difficulty with suck rest suck cycle and subcostal chest in drawing. On examination, they have hyperactive precordium with cardiomegaly and flow murmurs across pulmonary valve due to excessive blood flow. They may have tachypnea, tachycardia and other signs of CHF. One more clue in examination is presence of Harrison's sulcus which indicates the presence of high pulmonary blood flow since long time.

The features of low pulmonary blood flow in cyanotic heart lesions are mainly dyspnea on exertion, squatting episodes and hypercyanotic spell. On examination, they will have quiet precordium, no or minimal cardiomegaly and ejection systolic murmur of right ventricular outflow tract obstruction (although all cases will not have murmur like in pulmonary atresia there is no outflow tract obstruction murmur). Typically, they don't have predisposition to recurrent chest infections and other features of CHF (Unless there is secondary cause for CHF like anemia) due to protective effects of right ventricular outflow tract obstruction.

Objective assessment of pulmonary blood flow is by chest X-ray (Fig. 2). Signs of high pulmonary blood flow on chest X-ray will be cardiomegaly and increased pulmonary vascularity evidenced by more than 4 end vessels in the middle third of lung fields or more than 6 vessels traceable to lateral third of lung fields.

Assessment of pulmonary blood flow is very useful clinical assessment and management of most of the cyanotic heart lesions can be started after assessing the

Fig. 2: Chest X-ray showing high pulmonary blood flow. Note the proximal dilated pulmonary arteries and pulmonary vasculature extending up to distal third of lungs. Also seen are dilated end on vessels in middle-third of lungs

pulmonary blood flow. Medical management of CCHD with low pulmonary blood flow is mainly on the lines of TOF physiology. They are given β -blockers, plenty of fluids and measures to prevent iron deficiency anemia. The lesions which present with high pulmonary blood flow are managed with diuretics and digoxin till the surgical plan is formulated.

CCHD WITH LOW PULMONARY BLOOD FLOW (TABLE 4)

This group is characterized by tetralogy of Fallot (TOF) and various other defects presenting as TOF physiology namely tricuspid atresia, VSD and pulmonary stenosis (PS), DORV VSD PS, TGA VSD PS, corrected TGA VSD PS, pulmonary atresia with or without VSD and various other single ventricular anomalies with PS (Figs 3 and 4). Ebstein anomaly also behaves as CCHD with low pulmonary flow; due to lack of forward flow across right ventricular outflow tract and intracardiac right to left shunt across ASD/ PFO (Fig. 5). Similarly critical pulmonary stenosis also has low pulmonary blood flow and right to left shunt across interatrial communication (as ASD or

Table 4: CCHD with low pulmonary blood flow

- Tetralogy of Fallot
- Tricuspid atresia, VSD and PS
- DORV, VSD and PS
- TGA, VSD and PS
- VSD with PS
- AV canal defect with PS
- Pulmonary atresia with/without VSD
- Pulmonary atresia with various other malformations (Univentricular or biventricular)
- CTGA, VSD, PS
- Ebstein's anomaly
- Univentricular heart with pulmonary stenosis
- Miscellaneous complex malformations with obstruction to pulmonary blood flow

DORV=Double outlet right ventricle; TGA=Transposition of great arteries; CTGA=Corrected transposition of great arteries; PS=pulmonary stenosis.

PFO) causing cyanosis but this is grouped as Acyanotic congenital heart disease.

Typical features of TOF physiology are history of dyspnea on exertion, squatting episodes or cyanotic spells. As pulmonary blood flow is reduced in this subgroup, there is no propensity for recurrent chest infections, sweating or other manifestations of congestive heart failure. Examination in TOF physiology reveals quiet precordium, no cardiomegaly and ejection systolic murmur of right ventricular outflow obstruction. Second heart sound is usually single in TOF physiology (either due to absent P2 in pulmonary atresia, not heard due to posterior pulmonary valve as in TGA or DORV, delayed and soft P2 with dextroposed aorta in TOF with virtually single S2). In TOF physiology, if cyanosis is out of proportion to murmur or apex is left ventricular type, then lesions other than TOF must be given consideration. In case of TOF, longer the ejection systolic murmur (ESM) of outflow tract obstruction

better is the saturation and if patient has long ESM with lower saturations then lesions other than TOF should be considered. Multiple heart sounds and clicks with low pressure pansystolic murmur of TR should raise possibility of Ebstein's anomaly of tricuspid valve.

Chest X-ray in TOF physiology will show no cardiomegaly and diminished pulmonary vascular markings. Figure 3 shows a classical boot shaped heart with upturned right ventricular apex and low QP. Chest X-ray will also help in determination of type of apex. Right ventricular apex with oligemic lung fields will include the possibility of TOF, DORV, VSD with PS or pulmonary atresia with VSD (Remember pulmonary atresia patient will not have

Fig. 4: Chest X-ray showing left ventricular type of apex with pulmonary oligemia. There is no cardiac enlargement. Echo showed tricuspid atresia, VSD and pulmonary stenosis. This three-month-old child presented with resistant cyanotic spells and underwent immediate BT shunt surgery

Fig. 3: Classical chest X-ray of tetralogy of Fallot showing boot shaped heart (right ventricular type of upturned apex) with small hila and reduced pulmonary blood flow

Fig. 5: Chest X-ray showing cardiomegaly and typical box shaped heart seen in Ebstein anomaly. Pulmonary blood flow is oligemic. This neonate presented at day 3 of life with cyanosis when PDA got smaller and was started on prostaglandin E1 infusion to open PDA for improving saturations

ESM of right ventricular outflow tract obstruction). Left ventricular apex should point towards tricuspid atresia or pulmonary atresia with intact ventricular septum. Ebstein anomaly will have a box like configuration with enlarged right atrium, narrow upper mediastinum and enlarged leftward convexity of enlarged infundibulum (Fig. 5).

ECG has a tremendous value in the differential diagnosis of various lesions in TOF physiology. Right axis deviation (RAD), right ventricular hypertrophy (RVH) and early transition from V1 to V2 will point towards diagnosis of TOF (tall monophasic R wave in lead V1 and then abrupt change to rS pattern in lead V2 as in Figure 6) where as right axis deviation with counter clock loop and prolonged PR interval will favor diagnosis of DORV. Left axis deviation with counterclockwise depolarization (Q waves in lead I and aVL) will be seen in TOF with atrioventricular septal defect (AVSD). Left axis deviation with counter clock depolarization along with left ventricular hypertrophy (LVH) is a feature of tricuspid atresia (Fig. 7) where as normal/rightward QRS axis and clockwise depolarization with left ventricular hypertrophy is seen in pulmonary atresia with intact ventricular septum. Biventricular hypertrophy (BVH) will be a feature of TGA, VSD PS, DORV VSD PS and Eisenmenger. Typical ECG changes in Ebstein anomaly are Himalayan tall peaked P waves, prolonged PR interval, bizarre second QRS attached to preceding normal QRS (Fig. 8). Some of these Ebstein patients may have Wolff-Parkinson-White pre-excitation or supraventricular tachycardia. Atrioventricular conduction

disturbances varying from first degree heart block to complete heart block along with presence of Q waves in right precordial leads and absent Q waves in left precordial leads may suggest CTGA. Single ventricular anatomy may be manifested by stereotyped QRS patterns.

CCHD WITH HIGH PULMONARY BLOOD FLOW (TABLE 5)

This group of disorders encompasses complex cyanotic heart defects which has torrential pulmonary blood flow and present in early infancy with features of congestive heart failure (when neonatal pulmonary vascular resistance drops). This group of disorders is predisposed to early congestive heart failure and 90 percent of these patients, if untreated don't survive beyond their first birthday. Compared to their counterparts of acyanotic congenital heart disease with high pulmonary flow, they tend to present earlier at around 2 to 3 weeks of age with feeding difficulty where infant takes feed for a while, gets tired and leaves the breast and then again starts taking feed (suck rest suck cycle). Parents may notice sweating while feeds and subcostal chest in-drawing. They have difficulty in taking feeds, high energy expenditure due to increased work of breathing and repeated chest infections leading to failure to thrive. Some may have an episode of lower respiratory tract infection needing hospitalization as first presentation.³

Examination in such cases reveals minimal cyanosis (saturation in the range of high 80s and in some cases

Fig. 6: This patient presented with features of TOF physiology. ECG showing right axis deviation with right ventricular hypertrophy. Note the upright R wave in V1 and predominant S wave in V6 suggestive of right ventricular hypertrophy. Sudden transition of R wave in V1 to S wave in V2 is highly suggestive of TOF

Fig. 7: 12-lead electrocardiogram in a patient of tricuspid atresia demonstrating left axis deviation. Also note deep S waves in right chest leads and tall R waves in left chest leads indicative of left ventricular hypertrophy and very little right ventricular forces suggestive of small right ventricle. Also note tall P waves suggestive of right atrial enlargement, all typical features of tricuspid atresia

Fig. 8: ECG in Ebstein's anomaly of tricuspid valve showing right bundle branch block pattern with polyphasic and splintered QRS. The QRS is wide and lead V2 shows rS pattern mimicking right bundle branch block. Lead II shows multiple small deflections (splintered QRS)

above 90) which may be picked up by pulse oximeter only. Lower degree of saturation is due to high pulmonary blood flow going to lungs for oxygenation. Most of these patients will have signs of flow murmur in mitral/tricuspid valve and semilunar valves. Wide fixed S2 split along with signs of high pulmonary blood flow is seen in TAPVC, although in obstructed TAPVC features are mainly of pulmonary hypertension rather than increased pulmonary blood flow. TOF with absent pulmonary valve will have a “to and fro murmur” along with single soft S2 (only soft A2 heard due to dilated pulmonary trunk and P2 is absent due to absent pulmonary valve) giving an impression of sawing wood. Bounding pulses, single loud S2 with harsh ejection systolic murmur in left 3/4th intercostal space, radiating up and to right along with early diastolic murmur and ejection click is specific feature of truncus arteriosus.

Chest X-ray will confirm the high pulmonary vascularity and cardiomegaly. Absence of thymic shadow is commonly seen in CCHD high QP. Characteristic X-ray features can be seen in some cases. Few examples include dilated RA and RV in TAPVC (characteristic Snowman appearance seen only in supracardiac TAPVC as in Figure 9), dilated RA and RV along with massive dilatation of pulmonary trunk and proximal PA branches in TOF with absent pulmonary valve, egg on side appearance in TGA and high take off of pulmonary arteries in truncus arteriosus (Fig. 10).

ECG can be helpful in narrowing down the diagnosis. TAPVC has an rsR' pattern as seen in ASD. LAD with RVH/BVH in DORV Subaortic VSD with high pulmonary flow where as LAD with LVH is seen in tricuspid atresia. RVH is present in TGA, TAPVC, DORV and BVH is seen in truncus and TGA with VSD.

Table 5: Cyanotic congenital heart lesions with increased pulmonary blood flow

1. Tricuspid atresia with nonrestrictive ventricular septal defect
2. Transposition of the great arteries with patent ductus arteriosus or ventricular septal defect or both
3. Double-outlet right ventricle with VSD and without pulmonary stenosis
4. Truncus arteriosus
5. TOF with absent pulmonary valve
6. Univentricular heart with nonrestrictive pulmonary blood flow
7. Total anomalous pulmonary venous connection
8. Miscellaneous complex malformations without obstruction to pulmonary blood flow

CYANOTIC CHD: THE DIAGNOSTIC PATHWAY (TABLE 6)

The most important assessment is done by detailed medical history including antenatal drug intake by mother and perinatal events. Special emphasis should be to determine

Fig. 9: This is a six-month-old child who presented with right upper zone bronchopneumonia. Examination revealed wide fixed S2 split and saturation of 85 percent. Chest X-ray showing minimal cardiomegaly and wide upper mediastinum and increased pulmonary blood flow. Echo showed supracardiac type of TAPVC. Patient underwent surgical repair after treatment of bronchopneumonia

Fig. 10: Chest X-ray showing cardiomegaly with high pulmonary blood flow and narrow upper border of mediastinum. Note the proximal dilated pulmonary arteries and pulmonary vasculature extending up to distal-third of lungs. Also seen are dilated end on vessels in middle-third of lungs. This newborn presented with signs of congestive heart failure at 1 month of age and echo showed truncus arteriosus

Table 6: Cyanotic heart disease evaluation: specific points to remember

History (including prenatal, perinatal events)	Features of low pulmonary blood flow as cyanotic spell, squatting, dyspnea on exertion OR Features of high pulmonary blood flow as recurrent chest infections, failure to thrive, sweating while feeding and feeding difficulty.
Physical examination	Including degree of cyanosis, dysmorphism, femoral pulse palpation, determination of viscero-cardiac situs and detailed cardiac evaluation. Signs of high pulmonary blood flow as hyperactive precordium, cardiomegaly, hepatomegaly and flow murmur across pulmonary valve.
Chest X-ray	Look for situs, signs of high/low pulmonary blood flow, cardiomegaly and distinctive features of certain disorders like snowman appearance in supracardiac TAPVC, boot shaped heart in TOF, and egg on side appearance in TGA.
ECG	Mainly QRS axis and ventricular hypertrophy patterns. Also look for characteristic findings of ECG like Himalayan P waves in Ebstein anomaly, left axis deviation with absence of right ventricular forces in tricuspid atresia.
CT scan/ Angiographic studies	May be needed in some complex cases to delineate specific anatomy like pulmonary artery size or determination of preoperative hemodynamics as in single ventricular palliative procedures.

the onset of cyanosis and to determine features of high versus low pulmonary blood flow based on features described above. Examination should include assessment of cyanosis by pulse oximetry and determination of cardio visceral situs including detailed cardiac assessment with special emphasis on second heart sound (Table 7). Chest X-ray can help in the assessment of pulmonary vascularity, cardiomegaly and situs determination along with exclusion of pulmonary lesions. Look for classical X-ray and ECG features of specific diseases. ECG along with Chest X-ray can help in narrowing down the diagnosis in CCHD⁶ (Flow chart 1 to 3). For example, in a patient with right axis deviation with right ventricular hypertrophy, the most common lesions are TOF, DORV, pulmonary atresia, TAPVC and TGA. Chest X-ray in such cases will narrow down the subgroup with pulmonary plethora (TAPVC, TGA, DORV without PS) or pulmonary oligemia (TOF, pulmonary atresia, DORV VSD PS). Further differential can be made on the basis of predominant ventricular apex and knowledge of ECG and X-ray findings in a specific disease.⁶⁻⁸ This is important to note that neonatal cyanotic heart lesions have a different spectrum and hyperoxia test along with other methods to differentiate cardiac versus

Table 7: Characteristics of second heart sound (S2) in CCHD

Tetralogy of Fallot (TOF)	Single S2 noted. Only A2 heard on bedside despite being soft P2 also. Dilated and dextroposed aorta gives loud A2, severe PS leads to soft delayed P2
TOF with absent pulmonary valve	Single S2 (only A2 heard) due to absent pulmonary valve. A2 is soft due to dilated pulmonary trunk.
Pulmonary atresia	Single S2 (P2 absent and only A2 present)
TGA, CTGA, DORV and other malposed great arteries	Single S2 heard due to malposed great arteries (mainly posterior placed pulmonary artery)
Truncus arteriosus	Single S2 as only one truncal valve present
TAPVC	Wide fixed S2 split
Tricuspid atresia	Many combinations of tricuspid atresia seen. S2 usually single. Associated with pulmonary atresia (only A2), severe PS (soft delayed P2 may not be heard) or associated with malposed great arteries (where only one A2 heard due to posterior placed pulmonary artery)

Table 8: Common causes of cyanosis in neonates*Duct dependent pulmonary circulation*

- Pulmonary atresia, intact ventricular septum
- Pulmonary atresia, VSD and PDA
- Single ventricle with pulmonary atresia
- Severe forms of Ebsteins anomaly

Critical right ventricular outflow tract obstruction with intracardiac shunt

- Critical pulmonary stenosis with interatrial communication
- Tetralogy of Fallot with critical pulmonary stenosis
- Double outlet right ventricle, VSD with pulmonary stenosis

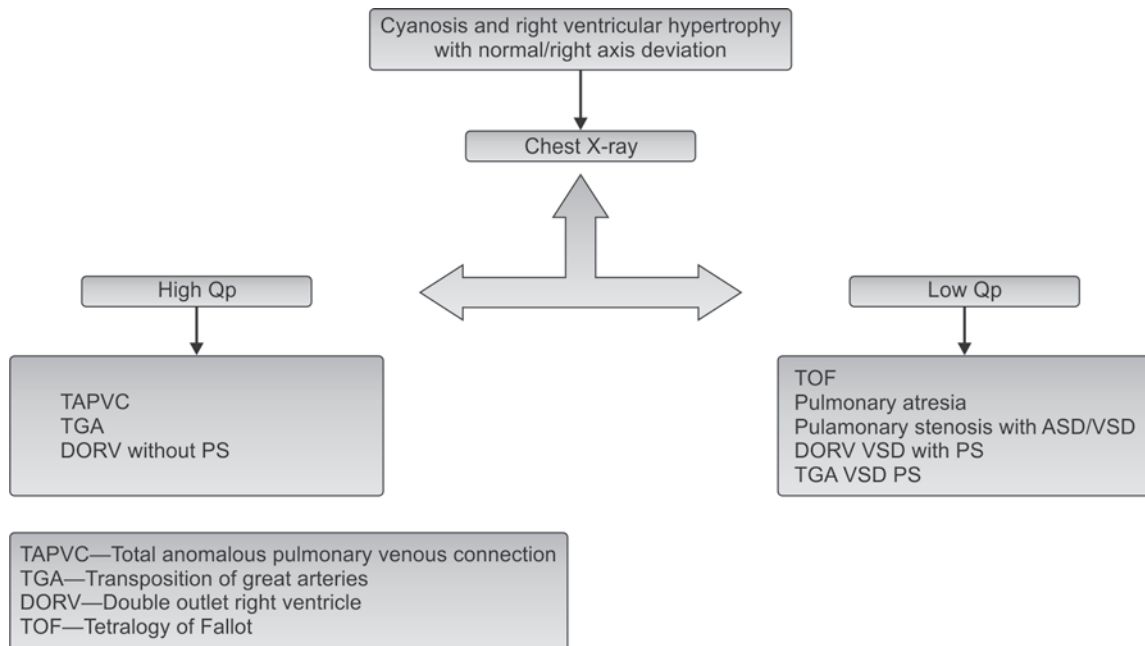

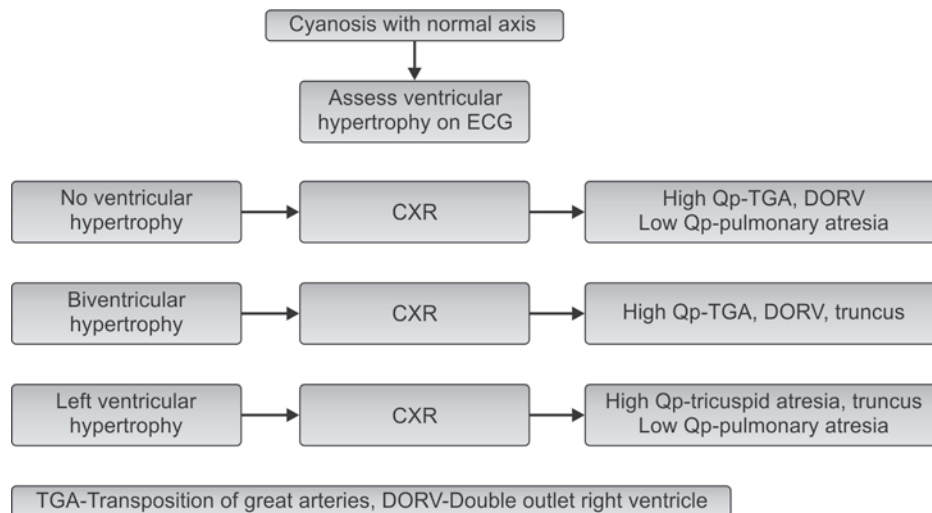

Admixture lesions

- Transposition of great arteries, intact interventricular septum
- Total anomalous pulmonary venous connection
- Truncus arteriosus
- Double outlet right ventricle with VSD
- Single ventricle anomalies with or without pulmonary stenosis

other causes of cyanosis are discussed in other chapters in this book which are dealing exclusively with neonatal cardiac diseases (Table 8).

SUMMARY

Cyanotic congenital heart disease (CCHD) is one of the most complex lesions in cardiology but a mathematical approach can be used to reach a diagnosis. There is no doubt that surprises will happen even with the most

Flow chart 1: A child with cyanosis and right ventricular hypertrophy on ECG**Flow chart 2:** A child with cyanosis and normal axis on ECG**Flow chart 3:** A child with cyanotic heart disease and left axis deviation

experienced clinician in this field, a thorough approach combined with Chest X-ray and ECG should be able to provide a working clinical diagnosis and management can be started before access to echocardiography.

Evaluation and Management of Arrhythmias in Children

Kiran Viralam

INTRODUCTION

“Cardiac Arrhythmia” refers to the absence of normal sinus rhythm in the heart. Pediatric arrhythmias pose a real diagnostic and therapeutic challenge. The management should be based on an accurate diagnosis obtained from firm foundation of clinical skill and judgment, with judicious use of latest diagnostic modalities. For the diagnosis, management and follow-up of pediatric arrhythmias use of technology is a must, it should optimize the treatment options and monitor the progress. As far as possible, treatment should not be started for a suspected arrhythmia without a baseline electrocardiograph (ECG), preferably a rhythm strip taken for at least 15 seconds duration.

Any treatment given for a potential arrhythmia can subsequently change the ECG tracing. It is virtually impossible to make a rhythm diagnosis on the basis of history and physical findings alone. Any wrong choice in pharmacological therapy initiated prior to diagnosis may have grave consequences on the overall health. However, short half-life drugs like adenosine or DC shock for hemodynamic impairment associated with arrhythmia are exceptions.

Interpretation of ECGs and management of arrhythmias form only a very small part of pediatric practice. Due to this, it is particularly hard to remain familiar with the nuances. Yet the stakes of mistakes are high. Failure to recognize that a syncope, seizure or cardiac failure is secondary to a cardiac arrhythmia may result in inappropriate treatment and a potentially preventable death.

ASSESSMENT

It is important to recognize that arrhythmias can be dangerous when:

- Heart rate is too fast or too slow to sustain cardiac output,
- Arrhythmia is incessant and unrecognized, or
- Arrhythmia is managed badly.

Coexisting structural heart diseases in children causing compromised cardiac function are particularly vulnerable to arrhythmias.

WHAT QUESTIONS TO ASK, WHAT ANSWERS TO SEEK?

During the initial triage, if the child is found hemodynamically compromised with ECG tracing showing arrhythmias, one should immediately proceed towards immediate rescue measures than spending time on detailed history. A tachyarrhythmic patient with hemodynamic instability may require DC shock and one with bradycardia and hemodynamic compromise may require temporary pacemaker insertion. Detailed history can follow once the hemodynamic stability of the patient is ensured.

Children can describe symptoms depending on their age and vocabulary. Older children can describe symptoms like palpitations, chest pain, dizziness, syncope, breathing difficulties or abdominal pain. It would not be inappropriate to ask objective leading questions, if the child finds it difficult to describe the problem, more so when the problem appears genuine.

Few questions that can help in the initial assessment of arrhythmias would be:¹

- How does an episode start and end?
- What precipitates such episodes?
- How frequently do they occur?
- How long does it last?
- How does the child react during such an episode?
- Has the child found or been taught some maneuvers to terminate the episodes?
- Have the parents found any associations with food or medications in the onset of such episodes?
- Is there a family history of arrhythmia, fits, syncope or premature sudden death?

In cases of younger children, especially infants, not much information can be found in history. Parental account of the problem would remain the source of vital clues. History of irritability and poor feeding of sudden onset without any apparent reason can make one suspect arrhythmias as a cause. Congestive heart failure (CHF) may result due to long standing untreated arrhythmias. Infants with features of CHF (sweating during feeds, tachypnea, easy fatigability, lethargy) in the absence of other explanations should draw attention towards a long standing untreated arrhythmia.

Clinical examination should be directed towards assessment of hemodynamic stability. It is usually normal in between attacks. Attention should not only be directed to the cardiovascular system to exclude structural heart disease but also to general examination to detect systemic disorders. Paroxysmal recurrent arrhythmias may have precipitating factors like fever, anemia, hyperthyroidism or structural cardiac diseases like Ebstein's anomaly or infectious causes like viral myocarditis. A careful clinical examination is helpful in determining these causes.

WHAT INVESTIGATIONS ARE REQUIRED?

The most important tool in the diagnosis of arrhythmia is a 12-lead ECG. Even if the child has already reverted to sinus rhythm, ECG would still be helpful in documenting baseline rhythm, axis, hypertrophy patterns, and abnormal configurations like delta wave. Evaluation of repolarization intervals like prolonged corrected QT interval (QTc) and short PR can be made on the baseline ECG.

HOW TO MEASURE QTc²

It is essential to measure the QTc. This is the value of QT corrected to the heart rate. Lead II and lead V5 are the leads to be used for measuring the QTc and the longer of these two should be reported as QTc. It should be remembered that all the measurements should be in seconds and not in milliseconds or number of small squares or big squares in the ECG. The TP segment forms the baseline of ECG. Measurement should begin at the onset of Q wave to the end of T wave, as defined by the point where the steep down slope of the T wave crosses the baseline. This value in seconds gives QT interval. The preceding RR interval is chosen and measured in seconds. The square root of this value should be measured. On dividing QT interval in seconds by the square root of preceding RR interval in seconds will give the value of QTc. A QTc more than 0.45 seconds in males and 0.46 seconds in females is suspicious and requires expert review.

The ECG recorded during the episode of arrhythmia is an invaluable tool for the diagnosis. If the arrhythmias are sporadic, wherein the arrhythmia ceases by the time an ECG is taken, 24-hour ambulatory Holter monitoring can

be very useful. However, when an episode of arrhythmia is much less frequent, an external event recording is handy tool. These recorders can either record continuous ECG tracings for a month or can be triggered to record an event of arrhythmia during symptoms.

If these modalities fail to give any conclusive evidence due to erratic and uncommon symptoms, one newly developed implantable loop recorder may be useful. These loop recorders are implanted in the pectoral region in a subcutaneous or subpectoral pocket and are active for 14 months. The monitor records a single-lead ECG after activation by the patient or parent or automatically, if a preset heart rate algorithm is triggered.³

HOW TO DIAGNOSE ARRHYTHMIA USING THE EVENT ECG?

A well defined algorithmic approach is utilized to diagnose the type of arrhythmia and to plan a treatment protocol. This approach can be used both for tachyarrhythmias (fast heart rate) and bradyarrhythmias (slow heart rate).

TACHYARRHYTHMIAS (Flow chart 1)⁴

Q1: *Narrow QRS complex or wide QRS complex?*

Narrow QRS complex arrhythmia implies normal conduction via AV node and Bundle of His. The QRS measures less than 0.1 seconds. Hence, they are also termed "Supraventricular." They are the most common arrhythmias encountered in children (Fig. 1).

In contrast, wide QRS complex arrhythmias originate usually below the His bundle often in the ventricles. The QRS measures more than 0.1 seconds. However, supraventricular tachycardias with preexisting bundle branch block or conduction aberrancy are exceptions, which occur proximal to AV node and His bundle, but still have wide QRS (Fig. 2).

The algorithm bifurcates here. The narrow complex tachycardia would be dealt first.

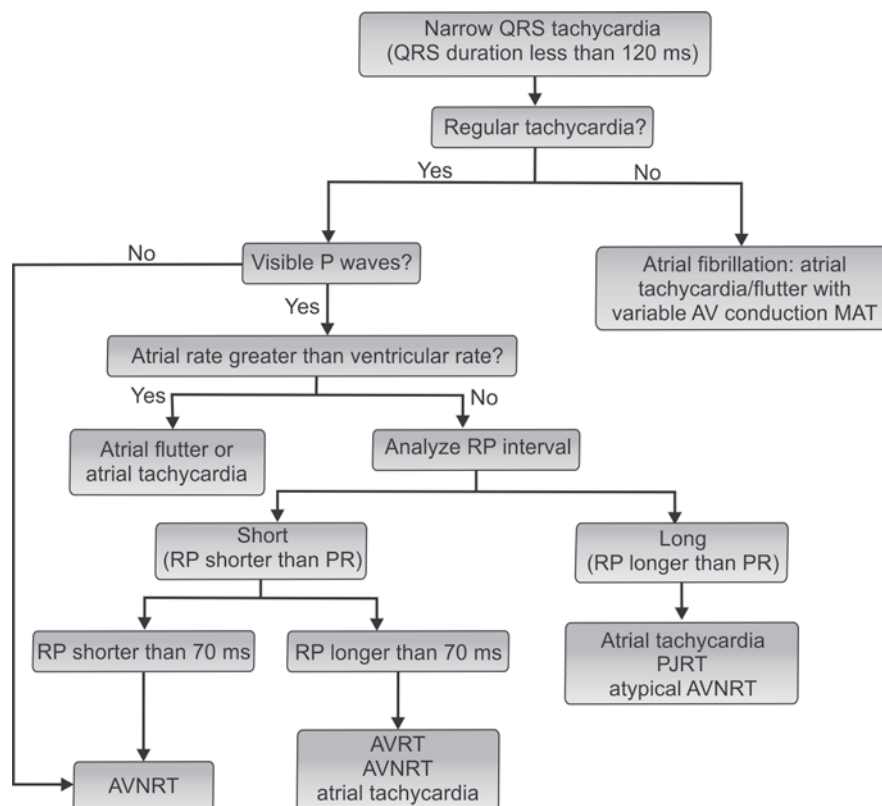

Q2: *Are the RR intervals regular?*

Irregular RR intervals occur either in atrial fibrillations or multifocal atrial tachycardia or atrial tachycardia with variable conduction. However, regular RR intervals need further assessment.

Q3: *Are the P waves visible?*

Analysis of P waves carries an important value. Hence, when the P waves are not visible on a superficial note, one should use few maneuvers to bring out the P waves. Some of these measures are:

- Increasing the speed of ECG tracing from a normal of 25 mm/sec to 50 mm/sec.
- Transesophageal recording with placement of an ECG electrode into the esophagus via the nasopharyngeal

Flow chart 1: Approach to diagnosis of Supraventricular tachycardia⁴**Fig. 1:** ECG tracing of a child with narrow complex tachycardia. Note that the QRS rate is around 250/minute and the width of QRS is less than 0.1 seconds

Fig. 2: Wide Complex Tachycardia. QRS duration is more than 0.1 seconds. Also note the fusion beats suggestive of ventricular tachycardia

approach. This probe will receive signals from the left atrium, which can then be compared with a simultaneous surface ECG.

If the P waves are not visible even after using the additional maneuvers, it signifies AV nodal re-entrant tachycardias (AVNRT), in which the P waves may get merged with the QRS. In this context, intravenous adenosine can help both in diagnosis and therapeutics. Intravenous administration of adenosine as a rapid bolus can be used to block the AV conduction. If the tachycardia breaks with adenosine, then it signifies AVNRT (Fig. 3).

Q4: What is P/ QRS ratio?

If P waves are seen, then the ratio of number of P waves to number of QRS complexes (P/QRS) should be assessed. P/ QRS of >1 (atrial rate more than ventricular rate) indicate atrial tachycardia or atrial flutter.

Fig. 3: Effect of intravenous adenosine on AVNRT. Continuous rhythm strip showing how AVNRT breaks into normal sinus rhythm with intravenous adenosine

However, if P/ QRS is less than or equal to 1 (atrial rate same or less than that of ventricle) then RP interval and PR interval should be measured. If the RP interval is longer than PR interval, it suggests atrial tachycardia, paroxysmal re-entrant tachycardia or atypical AVNRT.

If the RP interval is shorter than PR interval, it indicates short RP interval subgroup. In such cases, the actual RP interval should be measured. If the RP interval is less than 0.07 seconds, it usually signifies AVNRT. However, RP interval of more than 0.07 seconds is seen in AV re-entrant tachycardia or atrial tachycardia and in some occasions, AVNRT.

Q5. What if the QRS complex is wide (more than 0.1 second)?

Any tachycardia with wide QRS complex is considered ventricular in origin, unless otherwise proved. They originate distal to the bundle of His. The incidence of ventricular tachyarrhythmias is less than 5 percent of all arrhythmias in children amongst the general population. However, their incidence is high after cardiac surgery for congenital heart diseases and is linked to the mortality and morbidity. They can also occur with metabolic derangements, drug toxicity and myocarditis.

Fig. 4: ECG in Wolff-Parkinson-White Syndrome.⁵ Note the delta waves at the onset of QRS complex after the SVT got converted to Sinus rhythm. This indicates WPW syndrome

Fig. 5: ECG strip showing congenital complete heart block in a newborn. Note that there is no relationship between P waves and QRS complexes. Atrial rate is more than ventricular rate (P/ QRS more than 1). Also note that the QRS complexes are narrow, unlike in acquired complete heart block where QRS complexes are likely to be wide

Q6. Is there any relationship between P and QRS?

In classical ventricular tachycardia, there is no relationship between P and QRS. If the P/ QRS ratio is 1:1, then the possibilities would be SVT with aberrancy, SVT with bundle branch block, antidromic reciprocating tachycardia in Wolff-Parkinson-White (WPW) syndrome or rarely ventricular tachycardia with retrograde atrial conduction.

Q7. What are fusion beats and capture beats?

If a ventricular beat fuses with a sinus beat, the resultant beat is an intermediate complex and is termed a fusion beat. In capture beat, an atrial impulse passes through the AV node and stimulates the ventricle. The resultant beat is again an interpolated narrow complex. Fusion beat and capture beats are diagnostic of ventricular tachycardia.

Wolff-Parkinson-White (WPW) syndrome: This non-inherited condition needs special mention. Children with this condition have an accessory pathway capable of conducting forwards or backwards between the atrium and the ventricle. The result is an AV re-entrant tachycardia, with a higher risk for developing atrial fibrillation. The classical ECG finding is a delta wave, an upward wave at the onset of QRS complex. This results in short PR interval. Any symptomatic WPW should be referred at the earliest. Irrespective of symptoms, all children with a delta wave persisting after the fourth year of life should be seen by a pediatric electrophysiologist for opinion on electrophysiology study and subsequent decision on ablation (Fig. 4).

BRADYARRHYTHMIAS

Only a few causes of bradyarrhythmias are found in children.

Complete heart block (CHB): The ECG will show AV dissociation, with atrial rates faster than ventricular. The QRS complexes can be narrow as in congenital CHB or can be wide QRS complexes as in acquired CHB (Fig. 5).

Sinus node dysfunction: This entity presents with Adams-Stokes syncopal attacks. The ECG will show sinus bradycardia, inability to increase the heart rate during exercise and sinus pauses. It may occur after surgery for congenital heart diseases.

Bradycardia due to medications or poisoning is an important cause in children. Digoxin, beta-blockers, sedative-hypnotics, calcium-channel blockers, tricyclic antidepressants and organophosphorous pesticides can cause bradycardia.

Hence, in cases of unexplained bradycardia of recent onset, a toxicology screen is mandated.

MISCELLANEOUS ARRHYTHMIAS

Sinus Arrhythmia

The heart rate normally increases during inspiration and decreases during expiration. However, this process gets exacerbated in young children and adolescents. Sinus arrhythmia is a normal rhythm for age and does not require any work-up or therapy.

Premature atrial contractions (PAC): They are usually seen in infants and toddlers. If the cardiovascular examination is normal and electrolyte levels are maintained, PAC would be benign. Therapy is considered in infants only if associated with hemodynamic compromise.

Premature ventricular contractions (PVC): They are also seen in infants and adolescents. They are usually monomorphic. Their presence requires thorough cardiovascular examination, estimation of serum electrolytes, 24-hour Holter monitoring and echocardiography to rule out structural heart disease. If no cause is identified even with meticulous investigation, only they should be considered idiopathic. Such idiopathic PVC are benign, self-limited and are easily suppressed with exercise. Treatment is rarely required.

RARE BUT IMPORTANT ARRHYTHMIAS

High incidences of sudden cardiac death make few arrhythmias important, although their individual incidence is not high. Most of them would have molecular genetic basis. They are not amenable to radiofrequency ablation and would mandate the use of implantable cardiac defibrillator. Some of these arrhythmias are as follows:

Long QT Syndrome (LQTS)⁶

Prolonged QT syndrome is a congenital disorder of ventricular repolarisation characterized by prolongation of the

Fig. 6: Long QT syndrome². A rare example of an ECG showing gross prolongation of QT interval. Note the T wave alternans (thick arrows). This finding is said to precede Torsades de Pointes

QT interval on surface ECG. More common among them is Romano-Ward syndrome, a variant of LQTS with autosomal dominant inheritance. The Jervell-Lange-Nielsen syndrome having an autosomal recessive inheritance, is associated with congenital deafness and carries poor prognosis.

LQTS has underlying ion channelopathy affecting ventricular repolarisation, causing a polymorphic ventricular tachycardia called Torsades de Pointes, which can degenerate into ventricular fibrillation causing sudden cardiac death even in an apparently normal child. The usual symptom of LQTS is syncope precipitated by exercise or emotions. Hypoxic seizures are not uncommon and add up to the confusion in diagnosis. A total of 14 mutations have been recognized hitherto for LQTS.

Mortality is considerably reduced by use of beta-blockers. Long acting agents like nadolol is preferred. If the symptoms persist despite beta-blockade, an automated implantable cardiac defibrillator (ICD) should be considered. Small sized ICD units for pediatric population are now available, but would still require repeated revisions of electrodes as the child grows. A 'leadless' ICD which is being developed would eventually resolve this concern.

Beta-blockades should be continued even after ICD. (Fig. 6).

Catecholaminergic Polymorphic Ventricular Tachycardia⁷

This rare autosomal dominant condition affecting intracellular calcium transportation was described by Coumel et al. Children affected by this condition had syncope precipitated usually by exercise. Surface ECG in this condition shows a bidirectional ventricular tachycardia, which can deteriorate rapidly into a polymorphic ventricular tachycardia and sudden cardiac death. Beta-blockade would help, but persisting symptoms would indicate ICD implantation. (Fig. 7).

Arrhythmogenic Right Ventricular Dysplasia (ARVD)⁸

In this rare condition, the right ventricular myocardium is replaced by fibrofatty tissue. The surface ECG tracing shows T wave inversion in the right precordial leads with ventricular tachycardia of left bundle branch block morphology. ARVD has autosomal dominant transmission and is one of the causes of juvenile sudden cardiac death.

Fig. 7: Catecholaminergic polymorphic ventricular tachycardia.² ECG strip of an 8-year old boy with catecholaminergic polymorphic Ventricular Tachycardia during exercise. Note the normal QT interval, but multiple ectopics shown by asterisk mark and a short run of Ventricular Tachycardia shown by the arrow

Brugada Syndrome⁹

Much has been researched on this rare genetic arrhythmia. Syncope caused due to idiopathic ventricular fibrillation characterizes this condition. The typical ECG changes include right bundle branch block and variable ST segment elevation resembling coved or 'saddle type' in the right precordial leads. Brugada syndrome is a disease of young adults. Symptomatic events are commonly associated with febrile illnesses in the young and are usually nocturnal. Administration of sodium channel blocking drugs, such as mexilitine or flecainide sometimes bring about the ECG changes and is used as a diagnostic test too. There is no specific pharmacologic therapy for Brugada syndrome. Prevention and aggressive treatment of febrile illness and use of ICD for symptomatic children forms the treatment plan (Fig. 8).

Fig. 8: Brugada syndrome²

MANAGEMENT OF COMMON TACHYARRHYTHMIAS (Flow chart 2)¹⁰

Acute Management:

The purpose of acute management is to interrupt the arrhythmia or to slow down the response rate of ventricle. During an emergency, when the patient presents with hemodynamic compromise, the "ABCs" of resuscitation must be followed. Direct current cardioversion (0.5 to 1 J/kg, up to 2 J/kg) is considered in such situations, without wasting time on dissecting the nature of arrhythmia. If the

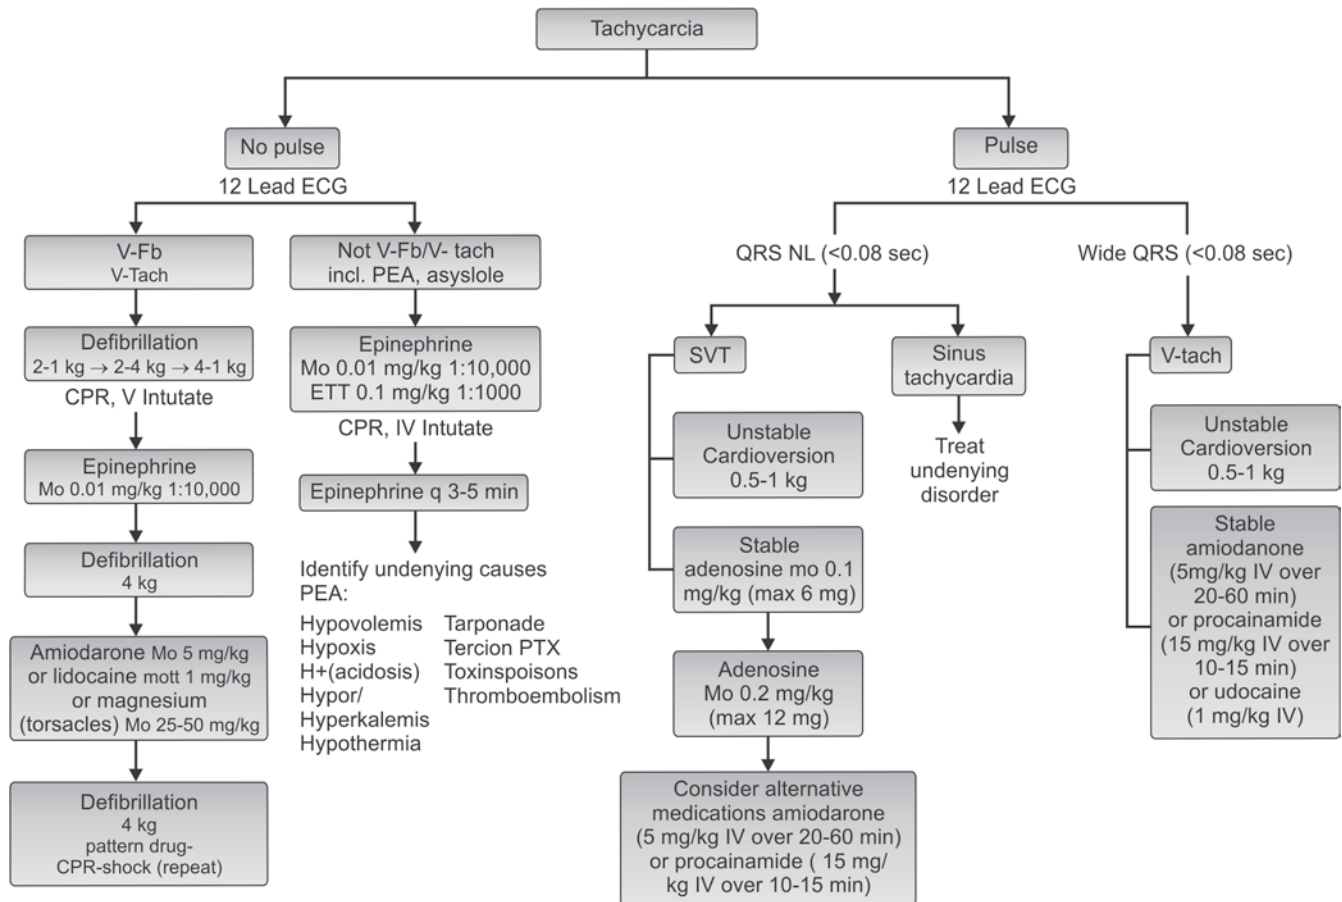

vitals are stable during the arrhythmia, the rhythm can be first evaluated by algorithmic approach explained previously and then treated.

The following are commonly used first-line measures:¹¹

Vagal Maneuvers

They are known to effectively terminate the SVT. In infants, keeping a bag of ice to the center of the face induces the diving reflex and is often helpful in terminating the SVT.

Flow chart 2: Management of tachycardia (PEA: pulseless electrical activity; SVT: supraventricular tachycardia; V-Fib: ventricular fibrillation; V-Tach: ventricular tachycardia).¹⁰ ECG strip of an 8-month old child with Brugada syndrome during fever. Note the right bundle branch block pattern and variable elevation of ST segment in V1 to V3 leads

- For aniodarone administration: repeat doses of 1-5 mg/kg (max amount 5 mg/kg) may be required depending upon patient stability and clinical scenario.
- For lidoozing administration: repeat every 5-10 minutes after initial doses, total dose 3 mg/kg after return of pertusion follow with acntinuous infusion 20-50 mg/kg/min.

In adolescents and older children Valsalva maneuver can be taught to derive similar effect.

Adenosine is the usual first-line medication. Due to its extremely short half-life, it is to be given as a rapid intravenous bolus into a vein close to heart. It interrupts the conduction through the AV node. The dose usually starts with 100 $\mu\text{g}/\text{kg}$ in children and 200 $\mu\text{g}/\text{kg}$ in infants to a maximum of 300 to 500 $\mu\text{g}/\text{kg}$.

Adenosine can also be used as an important diagnostic tool. It does not have any effect on the rate of ventricular tachycardia. However, it may slow the atrial rate and reveal AV dissociation. This will confirm the diagnosis. Adenosine does not produce any hemodynamic deterioration in VT and hence, can be used as a diagnostic tool when there is a strong suspicion of dissociation.

Adenosine can also be used to differentiate the mechanism of SVT. It unmasks pre-excitation by blocking the AV node and thereby increases conduction down an accessory connection. This is useful when accessory connections were previously not apparent. Alternatively adenosine may unmask changes in PR interval, which favours a diagnosis

of dual AV nodal pathway. In few instances of atrial tachycardias and atrial flutter with rapid ventricular response, diagnosis may not be obvious. In such cases, increased AV block and slowed ventricular rate after adenosine help in revealing the underlying atrial rhythm.

Other intravenous drugs used are esmolol, amiodarone, and procainamide. Intravenous calcium channel blockers are contraindicated in infants, as hypotension and sudden death are reported with IV verapamil. However, they can be used in older children and adolescents.

CHRONIC MAINTENANCE THERAPY^{11,12} (TABLE 1)¹¹

Long-term therapy is meant to prevent recurrences. The choice of therapeutic measure is decided by the type of arrhythmia and mechanism, which causes it. For example, re-entrant SVT in which the AV node is a part of the circuit should use therapies that block conduction through the AV node. Hence, situations where tachycardias have responded to adenosine it would be logical to start a drug which acts on AV node for long-term treatment.

Table 1: Commonly used antiarrhythmic agents in the pediatric population¹¹

<i>Antiarrhythmic agents</i>	<i>Doses</i>	<i>Side effects</i>
<i>Class 1</i>		
• Procainamide	<i>Oral:</i> 30–100 mg/kg/d every 6 hours	Nausea, vomiting, lupus like syndrome, pancytopenia, agranulocytosis, confusion
• Lidocaine	<i>Intravenous:</i> 1 mg/kg	Seizure, central nervous system symptoms, arrhythmias, respiratory distress, hypotension
• Mexiletine	<i>Oral:</i> 5–15 mg/ kg/ d every 8 hours	Nausea, vomiting, headache, tremor, dizziness, paresthesia, rash
• Phenytoin	<i>Oral:</i> 2–5 mg/ kg/ d every 12 hours after a loading dose of 10–15 mg/ kg	Rash, Stevens-Johnson syndrome, neuropathy, gingival hypertrophy
• Flecainide	<i>Oral:</i> 2–6 mg/ kg/ d every 8 hours	Arrhythmia, conduction disturbances, dizziness, blurred vision, headache
<i>Class 2</i>		
• Propranolol	<i>Oral:</i> 2–4 mg/ kg/ d every 6 hours	Hypotension, bronchospasm, hypoglycemia (in neonates), lethargy, depression
• Atenolol	<i>Oral:</i> 1–2 mg/ kg/ d every 12 hours	Lethargy, depression, bradycardia, postural hypotension, agranulocytosis
<i>Class 3</i>		
• Amiodarone	<i>Oral:</i> load of 10 mg/ kg every 12 hours for 5–14 days followed by maintenance of 5–7 mg/ kg/ day	Arrhythmias, prolonged QTc interval, hepatotoxicity, hypo- and hyperthyroidism, corneal microdeposits, photosensitivity, pulmonary fibrosis
• Sotalol	<i>Oral:</i> 80–160 mg/ m ² / d every 8 hours for infants or every 12 hours for older children	Arrhythmia, prolonged QTc interval, bradycardia, fatigue, dyspnea
<i>Class 4</i>		
• Verapamil	<i>Oral:</i> 4–8 mg/ kg/ d every 8 hours or every day SR form	Hypotension, bradycardia, cardiac decompensation (esp. in infants). Not used in infants.
<i>Miscellaneous</i>		
• Adenosine	<i>Intravenous:</i> 0.1 mg/ kg rapid bolus	Transient bradycardia and tachycardia, transient AV block
• Digoxin	<i>Oral:</i> Load of 30–40 mcg/ kg (depending on age) over 1st day followed by maintenance of 5–10 mg/ kg/ day every day or divided every 12 hours	AV block, arrhythmias, nausea, vomiting

Digoxin and beta-blockers are used as first-line oral therapy for SVT in children. In Wolff-Parkinson-White syndrome, digoxin and calcium-channel blockers are contraindicated as they enhance ante-grade conduction in the accessory pathway allowing a more rapid ventricular response during atrial flutter or fibrillation, precipitating ventricular fibrillation.

If the first-line therapy is ineffective in controlling SVT, then flecainide, procainamide, sotalol, amiodarone or verapamil (a class IV agent) can be tried.

For primary atrial tachycardias, digoxin or calcium channel blockers are used to slow the AV conduction to decrease the ventricular response rate. Beta-blockers, procainamide, flecainide, propafenone, amiodarone and sotalol are commonly

used to alter the electrophysiology of the atrial substrate to control such arrhythmias.

Radiofrequency catheter ablation has the advantage of being curative therapy, especially in older children and adolescents, if the arrhythmia substrate can be defined (such as accessory pathway, ectopic focus, AV nodal slow pathway etc). After 1990s, ablation has been more widely applied in children also. In infancy, ablation is reserved for refractory and life-threatening arrhythmias and not a routine procedure. There is still concern in the small heart as to long-term complications of the lesions produced.¹³

In the older child, ablation offers cure of arrhythmia and thereby helps in preventing side effects of medications. Success rates for ablation of accessory pathways are as high

Table 2: Management of specific arrhythmias^{2,12}

<i>Arrhythmia</i>	<i>Medications, measures and comments</i>
Atrial ectopic tachycardia	Radiofrequency ablation, if leads to hemodynamic impairment
Atrial fibrillation	Rare in children, WPW syndrome, ibutilide, dofetilide, digoxin, beta-blockers, calcium channel blockers, ablation, maze procedure
Atrial flutter	Digoxin, amiodarone or flecainide, cardioversion
Chaotic ectopic atrial tachycardia	Very rare in children, amiodarone, if symptomatic
Re-entry tachycardia secondary to accessory pathway	Most common SVT, beta-blockers, flecainide, amiodarone or a combination in refractory cases. Ablation in older children
AV nodal re-entrant Tachycardia (AVNRT)	Beta-blockers, flecainide, digoxin, ablation, permanent pacemaker
Incessant junctional reciprocating tachycardia	Ablation
Junctional ectopic tachycardia	Usually postoperative. Cooling, minimize inotropes, overdrive atrial pacing, correct electrolytes, sotalol, amiodarone, procainamide, Ablation
Ventricular Tachycardia (non-genetic)	Amiodarone, lidocaine, beta-blockers, phenytoin, cardioversion, ablation, ICD

95 percent. Caution has to be employed where pathways are close to the AV node and when considering ablation for AVNRT. Ablation is applicable to some VTs and has a special role in the treatment of arrhythmias after surgery for congenital heart disease.¹³

MANAGEMENT OF VENTRICULAR TACHYARRHYTHMIAS¹¹

Acute Management

Without exception, this again begins with the ABCs of resuscitation. DC cardioversion should be urgently performed for hemodynamically compromised patients (can start with 1 to 2 J/kg and can go up to 4 J/kg). Reversible causes like electrolyte imbalance and acidosis should be treated. Intravenous lidocaine at 1 mg/kg is the first-line drug. Intravenous procainamide and amiodarone are also useful.

Chronic Therapy

This should be directed at the cause of the ventricular arrhythmia. In patients who initially responded to IV lidocaine, oral mexiletine is useful for long-term therapy. Ventricular tachycardia due to long QT syndrome responds to beta-blockers.

Amiodarone can be used as second-line therapy. It is a very powerful drug and should not be used irrationally. It has class III action and some degree of beta blockade. It acts on atrial myocardium, the AV node and ventricular myocardium and also has minimal negative inotropic effect. However, the drug has a potential for serious long-term adverse effects including hepatotoxicity, thyroid dysfunction and photosensitivity. Reversible corneal microdeposits, are also reported. In adults, pulmonary toxicity is a known problem. But it is not major concern in children.¹²

Amiodarone is effective intravenously with a very long half-life and builds up in the myocardium. It can be used

in combination with digoxin for added AV nodal effect. However, amiodarone increases the level of digoxin and maintenance doses need to be reduced. Similar effect is also seen with flecainide.¹² Table 2 summarises the management of common arrhythmias.

MANAGEMENT OF BRADYARRHYTHMIAS¹¹

The initial management of bradycardia should be directed towards identification of the cause and cardiopulmonary resuscitation. Choices of pharmacologic interventions are atropine (0.02 mg/kg, IV, minimum 0.1 mg; maximum single dose: 0.5 mg in children and 1 mg in adolescents) or isoproterenol given as an IV infusion 0.05 to 0.5 µg/kg/min, titrated to desired effect. Isoproterenol is a sympathomimetic agent known to increase the heart rate. If drug therapy does not improve the situation, then a temporary transvenous pacemaker is indicated.

Pacemakers are the treatment of choice for symptomatic bradycardia. They are aimed at restoring as close a physiologic rhythm as possible. The indications are defined by AHA/ACC guidelines.¹⁴

- Symptomatic second- or third-degree AV block
- Symptomatic sinus node dysfunction
- Postoperative second- or third-degree AV block persisting for at least 7 to 10 days
- Congenital complete AV block with a wide QRS escape rhythm, complex ventricular ectopy, ventricular dysfunction, or ventricular rate less than 50 to 55 beats/minute (bpm) in an infant or less than 70 bpm in a patient with congenital heart disease
- Sustained pause-dependent ventricular tachycardia, such as in long QT syndrome.

CONCLUSION

The diagnosis of arrhythmia is largely mathematical and an effective management can be worked out on an algorithmic basis. A high index of suspicion and alertness is

required for decision making. The decision should be based on a firm clinical judgment and meticulous ECG evaluation. Monitoring the child throughout the course of management is vital for effective care. Judicious use of medications and appropriate use of radiofrequency ablation goes a long way in optimal management. Refractory arrhythmias require multidisciplinary collaboration from pediatricians, pediatric cardiologists, electrophysiologists, and geneticists. Current advances in clinical and molecular genetics have started to offer improved screening and condition specific treatment for many potentially life threatening inherited arrhythmias.

ACKNOWLEDGMENT

The author would like to acknowledge the help of Dr Shreesha Maiya, Consultant Pediatric Electrophysiologist, Narayana Hrudayalaya, Bengaluru for inputs and for providing permission to use some of the ECG strips from his personal collection in this chapter.

Surgical Management and Outcomes of Congenital Heart Diseases

Raja Joshi, Reena K Joshi

The prevalence of congenital heart disease (CHD) among live births is estimated at 4 to 9 percent.¹⁻⁴ These figures do not include the bicuspid aortic valve, with an incidence of 2 to 3 percent in live born infants.⁵⁻⁸ Congenital heart disease being defined as the presence at birth of a gross structural abnormality of the heart, great arteries, or great veins that is actually or potentially of functional significance. Included in this definition, though not being a structural heart problem are congenital complete heart block.^{9,10} Extrapolating from an average prevalence of 8 percent of live births there are approximately 200,000 new cases per year in India.¹¹ Approximately, half of these will require tertiary care attention in their early infancy. Surgery forms a major part therapeutic armamentarium for managing most of such lesions, hence a clear understanding of the type of surgeries, the optimum timing for these and their short and long-term outcomes are important to discuss.

Most heart surgeries for CHD can be classified as curative (No postoperative residua, sequel or complications), reparative (Anatomic repair or reconstruction with obligatory postoperative residua or sequel), palliative (basic morphologic anomaly is neither repaired nor reconstructed), reoperative (late reoperation after reparative or palliative surgery) and transplantations.

There are some common major late morbidities related to many types of repairs of congenital heart surgeries. These are late death, reintervention, heart failure/ventricular dysfunction, rhythm disturbances and need for pacemaker, endocarditis, exercise limitation and restrictions, neurocognitive impairment, decreased ability to tolerate pregnancy, need for chronic medications and impaired quality of life. Lesion specific outcome parameters are discussed below.

ATRIAL SEPTAL DEFECTS

Atrial septal defects of secundum variety are best closed at two years of age or anytime after that whenever diagnosed.

Indications of closure are symptomatic child, presence of cardiomegaly, dilated right atrium and right ventricle. Options available are surgical closure and percutaneous device closure. The surgical success for closure approaches 100 percent. Time related survival of patients operated for ASD during the first few years of life is that of the matched general population implying there is no late attrition of these patients and survival continues in the second decade and beyond. Features to follow carefully would be RV diastolic dimensions, (especially if the closure was performed at an older age), atrial arrhythmia. Those with atrial arrhythmias especially atrial fibrillation run the risk of thromboembolism and therefore need anticoagulation.

Sinus venosus atrial septal defects (SVASD) require to be surgically repaired as most of them will be associated with partial anomalous drainage of the pulmonary veins. A recently published study looking at long-term outcome of sinus venosus ASD noted outcomes which may be surprising. The authors reviewed outcomes of 115 patients (mean age 34 years) with SVASD who had repair. Complete follow-up was available in 95 percent patients at 144 + 99 months. Symptomatic improvement was noted in 83 patients (77%), and deterioration was noted in 17 patients (16%). At follow-up, 7 (6%) of 108 patients had sinus node dysfunction, a permanent pacemaker, or both and 15 (14%) of 108 patients had atrial fibrillation. Older age at repair was predictive of postoperative atrial fibrillation.¹²

Primum atrial septal defects also called partial atrioventricular septal defects need to be closed surgically. These infants get symptomatic earlier in case they have left atrioventricular valve regurgitation. Incidence of trisomy 21 with this lesion should also be kept in mind while working up these patients. Their follow-up reveals main reasons for long-term concern being left AV valve dysfunction (regurgitation/stenosis), left ventricular outflow tract obstruction and residual pulmonary hypertension.

VENTRICULAR SEPTAL DEFECTS

Ventricular septal defect is one of the lesions where the long-term outcome is excellent if no residual lesion has been left behind.¹³ Premature late death occurs in less than 2.5 percent of patient provided the pulmonary resistance was preoperatively judged to be low. Patient who had high preoperative pulmonary vascular resistance may succumb from progressive pulmonary vascular disease. Thus it must be emphasized that closure during the first year of life is curative.

If timely closure is done, physical growth normalizes for all parameters. Rarely, aortic or tricuspid valve regurgitation may be present related to preoperative or intraoperative issues.

Certain conduction defects can also be seen on the ECG in the long-term. These can be right bundle-branch block alone (about 40%) which are relatively benign, RBBB with left anterior hemiblock (about 15%) which run the theoretical disadvantage of a higher risk to develop late complete heart block ventricular arrhythmias (especially if the age at operation was older). Complete heart block is noted in small number of patients (<1%).

PATENT DUCTUS ARTERIOSUS

The preferred modality for closure of isolated patent ductus arteriosus (PDA) in a term infant is by a percutaneously delivered device. As an alternate therapeutic option surgical division can be undertaken. For very small for age and premature newborns with large PDA, the first line of management should be prostacyclin inhibitors. In case there is no response to the PCI therapy, a contraindication to such therapy or a recurrence after two courses of PCI, surgical ligation should be undertaken.

Follow-up should involve left pulmonary artery, coarctation and resolution of left ventricular dilatation. Life expectancy is normal after closure of an uncomplicated PDA in infancy or childhood with older age at operation or preoperative high pulmonary vascular resistance late deaths may result from progression of pulmonary hypertension. Comorbidities related to the prematurity of newborns are responsible for major long term issues.

COMPLETE ATRIOVENTRICULAR SEPTAL DEFECTS (AV CANALS)

These patients require early repair of the AV septal defect encompassing closure of the atrial and ventricular components and closure of the cleft in the left component of the common valve. Most long-term survivors (88%) are in excellent NYHA-status. These defect once repaired and are beyond the early hazard phase (which is steep for the initial 6 to 9 months after surgery) show a very small but appreciable constant hazard phase. This means that these patients need regular follow-up even in the long-term.

The main reasons for concern are left AV valve dysfunction (regurgitation/stenosis). Left ventricular outflow tract obstruction (more after a partial AV septal defect repair than complete), residual pulmonary hypertension, and rarely complete heart blocks or supraventricular arrhythmias.¹² It should be noted that presence of trisomy ²¹ does not adversely affect the outcome of these defects. Incidentally a study published in 1995 with follow-up of 203 patients concluded that mortality has decreased over the decades from 19 percent before 1980 to 3 percent after 1990. The 10-year survival is 90 percent and all patients are in NYHA class I or II. Late reoperation was required in only 8/203 patients and their results indicate that complete atrioventricular septal defects can be repaired with low mortality and good intermediate to long-term results.¹⁴

Coarctation of Aorta/Interrupted Aortic Arch

In isolated coarctation of aorta long-term survival is excellent. Long-term issues include resting and exercise induced hypertension. Recurrence of coarctation has to be sought for actively. Commonly associated bicuspid aortic valve may show signs of stenosis by the 2nd or 3rd decade of life and may also be a source to infective endocarditis. New or late onset subaortic stenosis is also an issue to be looked for. If patch aortoplasty was performed care should be taken to evaluate for aneurysm formation in the long run. Cerebrovascular accidents are more common in patients with persistent hypertension and in those with berry aneurysms.

In a late follow-up up to 50 years after coarctation repair, surprisingly 18 percent (45/274) patients died at a mean age of 34 years. Predictors of survival were age at operation and blood pressure at the first postoperative visit. The authors noted long-term survival is significantly affected by age at operation, with the lowest mortality rates observed in patients who underwent surgery between one and five years of age. More than one-third of the survivors developed significant late cardiovascular abnormalities.¹⁵

Interrupted arch mostly presents as a duct dependent lesion in a neonate. It is commonly associated with a ventricular septal defect. It is also commonly associated with DiGeorge syndrome. This cardiac lesion needs to be repaired in the neonatal period.

TRUNCUS ARTERIOSUS

Since a valved conduit is used for repair during the neonatal period, the issues related to the valve in the necessitate reoperation or intervention or both. Pulmonary vascular disease often develops and progresses in older infants

and children who did not undergo repair and therefore adversely affects survival in the long run. A recent single center review of 16 cases on intermediate-term follow-up indicate conduit and valve failure at mean follow-up of 2.5 years in 67 Percent of the patients.¹⁶

Tetralogy of Fallot

Tetralogy of Fallot (TOF) has the longest history of surgical treatment of any cyanotic lesion, with a 60 year history of palliation and a 50 year history of repair.¹⁷ The era of surgical therapy for cyanotic heart disease began in 1945 with Blalock and Taussig's report of palliation of three patients with TOF by systemic to pulmonary artery shunt.¹⁸ In 1955, Lillehei et al¹⁹ reported the first intracardiac correction of TOF. As the field moved into the 1990s, preoperative catheterization was replaced by echocardiography, and significant advances were made in postoperatively care. The fraction of patients palliated initially with a shunt continued to decline.

The Pediatric Cardiac Care Consortium (PCCC) reported that between 1991 and 1995, 22 percent of patients had a shunt before definitive repair.²⁰ The mean age at repair in this consortium decreased to 1.35 years, and mortality declined to 2.3 percent. Surgical management of neonates with critical CHD expanded, and several large centers adopted primary repair in cyanotic neonates with TOF as their preferred strategy.²¹ The optimal approach in this patient group—shunt followed by later repair or primary repair—continues to be debated in 2005, as illustrated elsewhere in this issue. Finally, the multiple genetic associations with TOF, most importantly the 22q11 deletion syndrome, were increasingly recognized.²² Many of these genetic abnormalities have significant implications for long-term outcomes that are hard to separate from the management of the cardiac malformation (e.g. neurodevelopmental outcomes).

Hirsch et al²¹ reported on their center's experience with complete repair of TOF in 61 neonates operated on between 1988 and 1999. There was one in-hospital death and four late deaths, with an actuarial survival of 95 percent at 5 years. Freedom from reoperation was 58 percent at 5 years. Excellent survival after TOF repair is achievable, even with operation in the neonatal period. However, the frequencies of morbidities well described among patients operated on circa 1975 are undefined for the infant who has undergone routine repair in the recent era.

Adults with TOF face the sequel of medical and surgical management strategies use during their infancy and childhood. From a clinician's perspective, they enjoy excellent actuarial survival rates, and reintervention has been infrequent. However, there is growing concern about the long-term effects of pulmonary regurgitation and ventricular dysrhythmias, with their attendant influences on functional status, exercise tolerance, and the risk (fear) of

sudden death. These late outcomes may or may not be applicable to the current generation of infants with TOF undergoing primary repair. Follow-up studies are needed in more contemporary cohorts to define their truly late outcomes.

This is a heterogeneous group of patients that behave in a variety of ways in long-term follow-up. To answer the difficult question regarding "surgical cure" of tetralogy we take lesson learnt from a large meta-analysis. This infers that time related survival of most patients after repair of TOF with pulmonary stenosis (not atresia) under proper circumstances is excellent, approaching that of general population, but the risk of death throughout life is "slightly greater" than general population.

During follow-up important point to be noted are RV function, RV outflow tract aneurysms, pulmonary insufficiency (especially if a transannular patch has been placed during the repair) residual right ventricular outflow tract (RVOT) obstruction and recurrent/residual VSDs, late aortic insufficiency, tricuspid valve competence and ventricular or supraventricular arrhythmias.

Progressive RV dilatation and dysfunction (preferably documented by MRI) should be sought for early. An ECG with QRS duration >180 ms puts these patients on a higher risk for sudden death from ventricular arrhythmias.

A recent study evaluated 95 patients with TOF on long-term follow-up for their RV function. Despite a large number of reoperations, this cohort of patients remained well with low incidence of sudden death with normal good RV and LV function. Aggressive intervention for right-sided hemodynamic abnormalities may have contributed to this outcome. Preserved ventricular function may herald a favorable long-term outlook in this group, the authors concluded.²³

In another multicenter study, 793 patients with tetralogy were reviewed for late arrhythmia complications. Thirty three patients developed sustained monomorphic ventricular tachycardia, 16 flutter or fibrillation. Pulmonary regurgitation was the main underlying hemodynamic lesion for patients with ventricular tachycardia and sudden death, whereas tricuspid regurgitation was for those with atrial flutter/fibrillation.²⁴

SINGLE VENTRICLE

This terminology comprises a wide variety of diagnosis. These patients have to be placed on what is termed as a single ventricle or Fontan palliation protocol.

The long-term survival issues cannot be simplified because of the heterogeneity of the primary diagnosis for which a Fontan pathway was offered. With the latest modification in the staged palliation towards Fontan operation mid-term survival is approaching and exceeding 90 percent. There is present the late slow rising phase of the baffle and this leads to some degree of acceptable cyanosis.

During the follow-up important facts to review and expect are development of supraventricular tachyarrhythmias, ventricular dysfunction, protein losing enteropathy, serous cavity effusions, thromboembolic and neurological complication (especially if a fenestrated Fontan is done). Development of AV valve regurgitation is detrimental and needs to be evaluated. Systemic hypertension and semilunar valve incompetence promote load on the ventricle and need prompt attention. Obstruction to the Fontan pathway and baffle leaks should also be looked into. These adolescents self learn to cope up with mild exercise intolerance.

In a recent review of 225 patients of double inlet single left ventricle (DILV) who underwent Fontan operation in Mayo Clinic between 1974 to 2011, median age at operation was 9 years and median follow-up was 12 year. The operative mortality after 1989 has decreased to 3 percent. Current health as described by the patients was good or excellent by authors concluded that, the Fontan operation for DILV is now performed with a low operative mortality rate. Long-term survival has improved, and most patients have good functional status.²⁵

TRANSPOSITION OF GREAT ARTERIES

Complete transposition of the great arteries is a relatively common anomaly, which comprises 5 to 7 percent of all instances of cardiac malformations. Palliation of D-TGA became possible in 1950 with the development of the Blalock-Hanlon atrial septectomy, which improved intercirculatory mixing.²⁶ A physiologic repair using native atrial tissue was first reported by Senning²⁷ in 1957, followed by Mustard's²⁸ success with an atrial switch using a pericardial baffle in 1963. Atrial switches became widely used in the 1960s and 1970s in a growing population of children stabilized in the neonatal period by a Rashkind transcatheter atrial septostomy.²⁹ In 1975, Jantene³⁰ reported the first successful arterial switch operation (ASO), ushering in a new era of surgery for D-TGA. Despite an initial difficulty with high operative mortality, the ASO had become the predominant surgical strategy at most institutions by the late 1980s.³¹

Given the decreasing mortality rates associated with a neonatal arterial switch operation and the unacceptable morbidity with atrial baffle operation and the unacceptable morbidity associated with atrial baffle operations, this operation has been accepted as the procedure of choice for the treatment of complete transposition of the great arteries. It restores the left ventricle to its natural systemic function. Long-term survival exceeds 90 percent. Translocation of the coronary arteries remains one of the most difficult aspects of the operation and late mortality appears to coincide with coronary artery events with sudden death secondary to acute myocardial infarction being

reported in 1 to 2 percent of hospital survivors. Supravalvar pulmonary Stenosis, neo-aortic root dilation and valvar regurgitation and myocardial perfusion abnormalities are aspects which require routine follow-up.³² Death hazard rate is extremely low by 6 to 12 months after an arterial switch operation and survival declined minimally after that time.

In the Third World countries, where timely referrals are difficult, there still is a role for the Senning's/Mustard's operations. The cardiac problem to be followed in these cases will be the failure of systemic right ventricle and systemic tricuspid valve regurgitation (pronounced more if repair was for TGA+VSD). Atrial arrhythmias are the next most long-term issue after these types of surgeries. A review of 40 years of experience of the atrial switch results highlighted 75 Percent 25 year survival. Late morbidity included issues mentioned above. Progressive heart failure necessitating surgery or late sudden death from arrhythmias is the main etiologies of late death.³³

By the mid 1990s the ASO had essentially completely replaced the atrial level switch, except in rare complicated anatomic or clinical situations. The first decade of routine use of the ASO was marked by a decline in the operative mortality rated in several large series^{34,35} and increasing success with complex coronary patterns. Dibardino et al³⁶ reported an overall 1.6 percent early mortality at their center since 1995; no patient was denied ASO on the basis of a coronary anomaly actuarial analysis of this series shows 96 percent survival and 90 percent freedom from reoperation at 7 years. In contrast, a publication from the PCCC using slightly older data (1992 to 1996) reported an overall hospital mortality of 15.1 percent with marked variation in mortality by center, ranging from 0 to 50 percent.³⁷ This study reminds us that publication bias favors good results, and although most results of the ASO in the literature are outstanding, a subset of patients may not be enjoying such outcomes. Finally, prenatal diagnosis became increasingly common in the 1990s and has been embraced by clinicians as a mechanism to improve outcomes; however, a beneficial effect on long-term outcome has yet to be demonstrated.³⁸ The medium- and long-term outcomes for D-TGA are reassuring, although older patients after atrial repair are at risk for arrhythmia, ventricular failure, and sudden death. Although these sequel are not likely to affect younger children with ASO to the same degree, new and emerging difficulties, such as coronary disease or aortic root dilation, may become the "Achilles heel" of the new approach. The transition of surgical management from the atrial to the arterial repair and its emerging sequel reminds us of two important facts: (1) Innovation based on past results is necessary to improve overall outcomes, and (2) naivete that the heart is "corrected" cannot replace systemic, comprehensive follow-up.

SUMMARY

Optimum late outcomes are the holy grail of medicine. Although the emphasis of innovation is often initially on short-term measures of success, the ultimate goal of therapy is improved long-term functional status and quality of life. Mortality associated with CHD has been declining approximately 39 percent over the past several years. This is true for all age groups and for all lesions. It would be safe to conclude that current practice patterns and strategies for patients of CHD offer them an excellent survival benefit and freedom from morbidities. Although these strategies have improved upon the natural history of most lesions, surgical (and now transcatheter) interventions have created an "unnatural history" that requires ongoing, lifelong, systematic follow-up.

Interventional Cardiac Catheterization in Children

Mangesh Jadhav, Snehal Kulkarni

INTRODUCTION

In the past 2 to 3 decades, the field of pediatric interventional cardiology has experienced significant growth. Technological innovations have greatly advanced treatment of cardiovascular disease in both children and adults with congenital heart defects (CHD). Most of the diagnosis of congenital heart defects is mainly done with two dimensional echocardiography. Sometimes additional noninvasive imaging like computed tomography or magnetic resonance imaging is used as additional tools of diagnosis. As a result, diagnostic procedures in the catheterization laboratory are decreasing and the catheterization laboratory is mainly used for interventional procedures.

Therapeutic catheterizations were initiated by Dotter and Judkins in 1964. Now, interventional therapy has become an acceptable alternative treatment for many congenital heart defects. Many of the procedures have already replaced surgeries. While selecting the patients for these procedures the indications, contraindications, risks involved in the procedures and cost implications need to be considered. *Along with the technical skills, anatomic and hemodynamic understanding, the knowledge of operator about the selection of hardware are most important parameters for the successful outcomes.*

The interventional procedures can be classified into emergency procedures, palliative and corrective ones. The emergency procedure is balloon atrial septostomy which is used to create a communication between the two atria for improving the oxygen saturations in patients with transposition of great vessels.

Other procedures can be classified as:

- Opening the valves and vessels-balloon aortic and pulmonary valvotomy.
Balloon dilatation and stent implantation of coarctation.
Balloon dilatation/stent implantation of pulmonary arteries

- Closing the intracardiac or extracardiac communications like closure of atrial and ventricular septal defects and closure of patent ductus arteriosus.
- Miscellaneous interventions—Closure of pulmonary AV malformations.
Closure of coronary AV fistulae.
Stenting of patent ductus arteriosus

ATRIAL SEPTOSTOMY

Balloon atrial septostomy (BAS), which was introduced by Rashkind and Miller in 1966 is a life saving procedure for patients with restrictive interatrial communication in transposition of great arteries, tricuspid atresia, total anomalous pulmonary venous connections. This is one of the few indications for an emergency catheterization in neonates. The procedure can also be performed in the intensive care unit under echocardiographic guidance.

Indications for atrial septostomy):¹

- To enhance atrial mixing (e.g. transposition of the great vessels with restrictive/ intact atrial communication) or to decompress the left or right atrium.
- For relief of left atrial hypertension, for example, in patients on extracorporeal membrane oxygenation support and in patients with hypoplastic left heart syndrome with an intact or restrictive atrial communication.
- For decompression of hypertensive pulmonary or systemic venous chamber with restrictive atrial communication (e.g. tricuspid atresia, pulmonary atresia with intact ventricular septum, total anomalous pulmonary venous connection) if needed before surgery.
- In selected patients with pulmonary arterial hypertension to increase cardiac output at the expense of increasing systemic desaturation.

Procedure²

Balloon atrial septostomy (BAS) can be performed either by femoral or umbilical venous route. Usually Rashkind's septostomy balloon is used for the procedure. The deflated balloon is introduced in the left atrium through the patent foramen ovale under fluoroscopic or echocardiography guidance. A rapid, short and forceful jerk is given to pull the inflated balloon towards the right atrium (Figs 1A to C). The procedure can be repeated three to four times till there is no resistance and oxygen saturation is improved.

BALLOON AORTIC VALVOTOMY (BAV)

The clinical spectrum of congenital aortic stenosis varies from normal function of a malformed bicuspid aortic valve to severe aortic stenosis (AS) in fetal life resulting in hypoplastic left heart syndrome. Congenital bicuspid aortic valve occurs in 1.3 percent of the population and is one of the most common congenital heart malformations³ (Figs 2A and B). In neonatal critical AS, congestive heart failure and shock occurs around the time of natural PDA closure. In older children, the presentation could be detection of systolic ejection murmur characteristic for valvular AS.

N; noncoronary cusp, L; left coronary cusp, R; right coronary cusp, LA; left atrium, LV; left ventricle, Ao; aorta
American College of Cardiology/ American Heart Association guidelines for balloon aortic valvuloplasty:⁴

- Asymptomatic children and young adults with Doppler peak instantaneous gradients of 70 mm Hg and/or catheter measured peak-to-peak gradient of >60 mm Hg.
- Patients who desire to participate in competitive sports or are contemplating pregnancy and have Doppler peak gradients between 50 and 70 mm and/or peak-to-peak gradient is >50 mm Hg.
- Patients with symptoms (angina, syncope, dyspnea on exertion) or ischemic or repolarization changes on rest or exercise ECG, if the peak-to-peak gradient is >50 mm Hg.
- Other causes of the symptoms or ECG changes should be sought if the gradient is <50 mm Hg.
- Valvuloplasty is not recommended for asymptomatic patients with peak-to-peak gradients <50 mm Hg unless cardiac output is impaired, in which case the gradient underestimates true severity of the obstruction.

Figs 1A to C: Echocardiography guided balloon atrial septostomy: subcostal long axis view showing inflated balloon in the left atrium A, The balloon is pulled into the left atrium B, and the defect in the interatrial septum at the end (arrow) C.

Figs 2A and B: Morphological specimen showing normal tricuspid aortic valve A, stenosed bicuspid valve B and echocardiographic images showing normal tricuspid valve in parasternal short axis view A, and stenotic bicuspid aortic valve in parasternal short axis view B

Procedure I

It is usually performed retrogradely with a catheter introduced through the femoral artery. An end-hole catheter is passed from the femoral artery across the aortic valve to a stable position in the left ventricle. With the wire secured within the left ventricle, the deflated balloon is passed retrogradely over the wire. The balloon is chosen with a diameter of about 80 to 90 percent of the measured aortic annulus diameter.⁵ Once the balloon is positioned across the stenotic valve, the balloon is rapidly inflated to the recommended maximal pressure and then rapidly deflated (Figs 3A and B). The procedure could be repeated till disappearance of the waist. After the procedure the gradient should be reduced by 60 to 70 percent or to <30 to 40 mm of Hg without significant aortic insufficiency.²

Complications

Femoral artery damage, bleeding, limb ischemia and aortic insufficiency which may progress over a period of time.⁶ The procedure is safe with complication rate of <3 Percent with the newer catheters and balloons.⁷

Balloon Pulmonary Valvotomy (Figs 4A and B)

Pulmonary stenosis (PS) at some level, with and without other associated lesions, occurs in 25 to 30 percent of all patients with CHD. Isolated pulmonary valve stenosis is found in 80 to 90 Percent of all patients with right ventricular outflow obstruction (RVOTO). Most patients with valvar pulmonary stenosis are asymptomatic. Symptoms due to right ventricular failure typically present in those with severe stenosis. Children with valvar pulmonary stenosis usually have normal growth and development regardless

of the severity of obstruction. Infants with critical pulmonary stenosis are cyanotic at birth, and the cyanosis may be severe enough to be life-threatening.²

Balloon pulmonary valvotomy is safe and effective therapy (BPV) for valvar pulmonary stenosis.⁸

Recommendations for pulmonary valvuloplasty¹ (Fig. 5):

- Indicated in patients with critical PS (presenting in neonatal age with cyanosis and ductal dependent circulation), severe PS with mean Doppler gradient of >40 mm Hg or with significant RV dysfunction.
- Reasonable in patient with dysplastic pulmonary valve and who satisfies above mentioned criteria.
- May be considered in cyanotic patients as a palliative measure, for example, tetralogy of Fallot.
- Contraindicated in patient with pulmonary atresia and RV dependent coronary circulation.

The balloon selected for the procedure is ideally 120 to 130 percent of the size of pulmonary valve annulus.⁹ Neonates with critical PS and a closed arterial duct, a low-profile balloon with fairly rapid deflation characteristics such as the Tyshak II balloon should be used. High-pressure balloons may also be more beneficial when dealing with very dysplastic, thickened pulmonary valves in the older patient, or if there is associated supralvalvar narrowing (Fig. 6).

Restenosis after balloon dilation is rare. Pulmonary regurgitation after dilation is common, which occurs in 10 to 40 percent of patients. Compared with surgical valvotomy, however, the incidence and severity of regurgitation is much lower in the group treated with valvuloplasty.¹⁰

Complications

Vessel injury, bleeding, limb ischemia.

Figs 3A and B: (A) Aortogram in lateral projection profiling the doming aortic valve annulus, (B) Balloon inflation centered across the aortic valve

Figs 4A to E: A and B: The echocardiography image of pulmonary valve in parasternal short axis showing stenotic valve with doming of cusps A, Color Doppler through the stenotic pulmonary valve shows a mosaic pattern; C: Continuous wave Doppler imaging in a patient with pulmonary valve stenosis. Note the peak pressure gradient of 61 mm Hg with concurrent pulmonary valve insufficiency; C and D: The ventriculogram in anteroposterior view D and lateral view E, showing stenotic pulmonary valve and characteristic doming of the cusps and dilated segment of MPA. RV: Right ventricle, Ao: aorta, MPA: main pulmonary artery, PV: pulmonary valve. (For color version see plate 17)

TRANSCATHETER DEVICE CLOSURE OF SEPTAL DEFECTS

Secundum Atrial Septal Defect

Secundum atrial septal defect (ASD) account for 7 percent of all congenital heart defects. The most common ASD is a secundum defect followed by defects located in the septum primum, sinus venosus defects, or unroofed coronary sinus. If left untreated, these defects may result in right-sided heart failure, arrhythmias, and pulmonary arterial hypertension. The first transcatheter closure of ASD in humans by double umbrella device was done by King et al in 1976.¹¹ Device closure of secundum ASD is associated with low complication rates, short anesthetic times, and short hospitalizations. When conditions are favorable,

transcatheter secundum ASD closure has become the treatment of choice. Echocardiography, either intracardiac or transesophageal (TEE), plays a significant role in the guiding these procedures.

Indications for Transcatheter Closure of ASD¹

- In patients with hemodynamically significant ASD with suitable anatomic features. The most important criteria to decide regarding the suitability is presence of adequate sized surrounding rims which will hold the device after deployment.
- In patients with transient right-to-left shunting at the atrial level who have experienced sequelae of paradoxical emboli such as stroke or recurrent transient ischemic attack.

Fig. 5: Schematic illustration of the catheter course and the position of balloon valvuloplasty catheter across the pulmonary valve.

Procedure: After prograde catheterization RV angiogram in lateral and AP projection is obtained. After assessing the details of valve size and location a long exchange guidewire is passed through an end-hole catheter into a distal pulmonary artery, preferably the left pulmonary artery. The balloon catheter is then negotiated over the wire and balloon is positioned across the valve. The balloon is later inflated and deflated rapidly till the disappearance of waist

Fig. 6: Single balloon technique of balloon pulmonary

Fig. 7: The amplatzer septal occluder (ASO) is a double-disc device formed of 0.005-inch nitinol mesh. It consists of two disks that are linked to each other through a central connecting waist. Dacron fabric is incorporated into each disk as well as the connecting waist to enhance thrombosis. The device size is defined by the diameter of the connecting waist and is available from 4 to 40 mm. The connecting waist has a length between 3 and 4 mm with the diameter of the left atrial disk exceeding the connecting waist by 12 to 16 mm, whereas the diameter of the right atrial disk exceeds the connecting waist by 8 to 10 mm

Devices for Secundum ASD Closure

Various devices have developed after efforts by King et al.¹¹ Currently, amplatzer septal occluder (AGA Medical) (Fig. 7) is the most widely used device worldwide. Other devices like HELEX septal occluder (WL Gore and Associates) (Fig. 8), cardioseal devices are also approved for secundum ASD closure in certain situations.¹ Both devices can be implanted successfully in children less than 2 years of age, although common practice suggests that a weight of 15 kg may offer some technical advantages and simplify the procedure.²

Procedure²

It is usually performed under general anesthesia under transesophageal echocardiography (TEE) or intracardiac echocardiography (ICE) as guidance. Complete prior echocardiographic assessment for the defect size, surrounding rims, pulmonary venous drainage, atrioventricular valves and associated cardiac malformation needs to be done.

Through the femoral venous access, the left upper or lower pulmonary vein is entered using either a wedge, multipurpose, or Judkins right coronary catheter, and a preshaped exchange length, extrastiff, J tipped wire is advanced. The device size is 125 percent of the average diameter of ASD assessed on TEE. Once the device size has been determined, the appropriate delivery sheath is

- In patients with a small secundum ASD who are believed to be at risk of thromboembolic events (e.g. patients with a transvenous pacing system or chronically indwelling intravenous catheters, patients with hypercoagulable states).

Contraindications for Transcatheter Device Closure of ASD

- In patients with ASD's other than those of the secundum variety like sinus venosus or ostium primum defects.
- Patients with advanced pulmonary vascular obstructive disease.
- Insufficient surrounding rims.

Fig. 8: Helex septal occluder: Its frame is made of a long nitinol wire, with a strip of polytetrafluoroethylene (PTFE) fabric attached alongside. Three eyelets are embedded along the device to facilitate accurate positioning, one at each end and one in central position between both disks. In its deployed status, the device forms two circular disks that are composed of the spiraling nitinol wire with its attached PTFE membrane. The device is available in sizes from 15 to 35 mm. It is used for closure of defects less than 18 mm in size¹²

placed over the guidewire. The dilator and wire are gently removed, and extreme care has to be taken to avoid any inadvertent air entry into the sheath and left atrium at this stage. The device is then prepared for delivery. The device is then loaded into the delivery sheath pushed forward under fluoroscopic guidance to the tip of sheath. The deployment is conducted under simultaneous echocardiographic and fluoroscopic guidance.

Complications

Device migration; device malposition; cardiac erosion/perforation leading to tamponade and death; atrioventricular block; and the complications encountered from a cardiac catheterization, including air embolism, infection, and hematomas.¹

Postprocedure Care

Usually the patients are advised to take tab aspirin 3 to 5 mg/kg daily for 6 months. They can do daily regular activities but they are advised not to participate in heavy competitive sports for six months.

Ventricular Septal Defects (VSDs)

Ventricular septal defects (VSDs) account for 20 percent of all forms of CHD.¹³ The ventricular septum can be divided into 4 regions: Membranous, inlet, trabecular, and outlet. Amongst all types of VSDs, only muscular and some types

Figs 9A and B: Device description:

A. Amplatzer MVSD occluder: It is a double-disk device made of 0.0005-inch nitinol mesh wire. Both disks are equal in size and exceed the diameter of the central connecting waist by 8 mm. Dacron fabric is incorporated into both disks as well as the central connecting waist, which has a length of 7 mm to accommodate the increased septal thickness of muscular VSD. It is available from 4 to 18 mm sizes.²

B. Amplatzer membranous VSD occluder: The membranous VSD occluder is an asymmetrical double-disk device made of 0.004-inch nitinol wire mesh. The asymmetrical LV disk exceeds the central connecting waist at the superior, aortic end by just 0.5 mm and at the inferior, apical end by about 5.5 mm. The RV disk is symmetrical to the connecting waist and exceeds its diameter by 4 mm at both the ends.²

of membranous VSD's are suitable for transcatheter closure with the help of device.

Patient selection for device (Figs 9A and B) closure (Figs 10A and B) is mainly done on the basis of transthoracic echocardiography.

Recommendations for Device Closure of MVSDs¹

- Weigh >5 kg child with hemodynamically significant* mid-muscular ventricular septal defect (MVSD) (*hemodynamically significant—left ventricular or left

Figs 10A and B: Procedure:² The procedure is performed under general anesthesia using continuous TEE and fluoroscopy guidance. Through retrograde approach the VSD is usually crossed from the LV using a Judkins RCA catheter with the help of a guide wire which is snared from the venous side. The appropriate-diameter long-delivery sheath is advanced over the guidewire through the defect into the left ventricle. Rest of the device delivery is similar to that of the Amplatzer septal occluder for ASD closure

atrial volume over-load or pulmonary-to-systemic blood flow ratio $>2:1$)

- Weight <5 kg child with hemodynamically significant MVSD and associated cardiac defects requiring cardiopulmonary bypass and may be considered for hybrid periventricular closure of the VSD off bypass.
- Distance of >4 mm between the margins of VSD and the aortic, pulmonic, mitral, or tricuspid valves.
- Pulmonary vascular resistance <7 indexed wood units.

Exclusion Criteria

- Weight <3.0 kg (unless the hybrid periventricular approach is used in this case);
- Sepsis
- Inlet VSD's with inadequate space between the defect and the atrioventricular or semilunar valves should not undergo device closure (hybrid or percutaneous).
- Small to moderate-sized MVSD (without symptoms) in whom there is a reasonable expectation that the defect will become smaller or may close over time.
- The angiogram showing closure of PM VSD. Left before closure and right after closure.

Complications¹

Device migration/embolization, tricuspid and mitral valve regurgitation, hemolysis, transient ischemic attack/ stroke, ventricular tachycardia, and complete atrioventricular

heart block especially with perimembranous VSD. The reported incidences of complete heart block is 4 to 6 percent.

TRANSCATHETER PATENT DUCTUS ARTERIOSUS OCCLUSION

Except in newborns and small infants, most of the transcatheter patent ductus arteriosus (PDAs) are closed by transcatheter closures in the cardiac catheterization laboratory (Fig. 11). For small PDAs either single or multiple coils are used for closures. For larger PDAs a device is used for closure.¹⁴ The most commonly used device to close medium- or larger-sized arterial ducts is the amplatzer duct occluder (ADO).² Although original recommendation for ductal occlusion excludes patients weighing less than 6 kg, successful use in infants as small as 2.5 kg has been reported, although such patients are more challenging technically.¹

RECOMMENDATIONS FOR TRANSCATHETER PDA OCCLUSION¹

- All the auscultable PDAs need to be closed for the risk of infective endocarditis.
- All small to large sized PDAs with left-to-right shunt can be closed by transcatheter closure provided the anatomy and patient size are suitable.

PDA closure is not recommended in a patient with a PDA with severe pulmonary hypertension associated with bidirectional shunt or PDA dependent systemic or pulmonary circulation.

Procedure²

Coil occlusion of the arterial duct can be performed using either an antegrade or retrograde approach. For very small PDAs, a retrograde arterial approach is usually sufficient.

Fig. 11: The device is mushroom shaped and made of 0.005-inch nitinol wire mesh. The central skirt of the device is cone shaped with the pulmonary end being about 1 to 2 mm smaller than the aortic end. The aortic end exceeds the diameter of central skirt by 4 to 6 mm. A micro screw for attachment of the delivery cable is recessed into the pulmonary end of the device. It is available from 5/4 mm to 16/14 mm. The total length of the device ranges from 5 to 8 mm²

Before crossing the patent arterial duct an aortogram is performed. Measurements are obtained at the pulmonary arterial end and the aortic end, as well as the total length of the arterial duct. A coil usually twice the size of the pulmonary end of the duct is chosen, and coils are deployed in a way to usually allow about one loop being placed distal to the pulmonary arterial end, while the remainder of the loops are placed in the ductal ampulla. For the device closure, the PDA is crossed by antegrade approach and a 0.035-inch exchange-length wire is advanced into the descending aorta. The appropriate delivery sheath is advanced over the wire. The selected device size is 2 mm larger than the size of the narrowest pulmonary arterial end of the arterial duct and the device is deployed through the sheath (Figs 12A and D).

Complications

Inadvertent device embolization into the pulmonary and systemic circulation; obstruction of the descending aorta or left pulmonary artery due to protrusion of disc especially in small infants; transient left ventricular systolic dysfunction; hemolysis; and recanalization of PDA.¹

Coarctation/Recoarctation of Aorta

Coarctation of the aorta is a common form of CHD, accounting for 6 to 8 percent of all cardiac defects (Figs 13A and B). Clinical manifestations of coarctation are age dependent. Neonates with coarctation of the aorta may present with signs and symptoms of low cardiac output and shock once the ductus arteriosus closes. Older infants and children may present with signs and symptoms of failure to thrive, and older children and adults may present with hypertension, headaches, and claudication.¹

Treatment of coarctation of the aorta has evolved over the last few years. Surgical repair of coarctation is the treatment of choice for neonates and small infants with

Figs 12A to D: (A) Angiogram in the descending aorta demonstrating a 2-mm patent ductus arteriosus (PDA) at its narrowest diameter (arrow), angiographic type A, (B) A 6 F delivery sheath across the PDA into the descending aorta with the device near the tip of the sheath (arrow), (C) Deployment of the retention disk and tubular part of a 6- to 4-mm Amplatzer duct occluder (arrow), (D) Final angiogram after the device has been released, demonstrating complete closure of the ductus

severe coarctation due to very high risk of recoarctation and femoral artery damage in this age group.¹⁵ Balloon dilatation with or without stent implantation is the treatment of choice in all children and young adults and in small children who develop recoarctation after initial surgical repair (Figs 14A and B and Figs 15A to D).¹

RECOMMENDATIONS FOR TRANSCATHETER BALLOON ANGIOPLASTY OF COARCTATION/ RECOARCTATION OF THE AORTA¹

- Transcatheter systolic coarctation gradient of >20 mm Hg and suitable anatomy.
- Transcatheter systolic gradient of <20 mm Hg and in the presence of significant collateral vessels and suitable angiographic anatomy or with significant ventricular dysfunction.
- In patients beyond 6 months of age when associated with a transcatheter systolic coarctation gradient >20 mm Hg and suitable anatomy.

Stent placement is indicated in patients with recurrent coarctation in bigger children or young adults in whom the stent can be expanded to an adult size, and who have a transcatheter systolic coarctation gradient >20 mm Hg.¹

COMPLICATIONS

Femoral artery injury, dissection, and aneurysm formation at the site of angioplasty, potential risk of stent malposition. The incidence of aneurysm formation after stent implantation is, less than for balloon angioplasty alone. The recoarctation rate after balloon dilatation is higher for younger patients (<6 months of age), and there is a small but definite risk of aneurysm formation after balloon dilation of native coarctation at any age.

Figs 13A and B: (A) The Three-dimensional reformatted CT angiogram in a left-lateral projection showing discrete coarctation and a tortuous transverse arch and isthmus, (B) The aortogram showing typical discrete juxtraductal coarctation with moderated poststenotic dilatation. (For color version see plate 17)

MISCELLANEOUS PROCEDURES

Patent Ductus Arteriosus Stenting

Stenting of the ductus arteriosus is considered in neonates and small infants to establish a reliable source of pulmonary blood flow for palliation of cyanotic heart disease with PDA dependent pulmonary circulation. This procedure is performed instead of doing a BT shunt operation to restore the pulmonary blood flow. Most of these patients are prostaglandin dependent or are severely cyanotic due to significant restriction of pulmonary blood flow. It is contraindicated in patients whose pulmonary arteries are of very small size.

Procedure

The PDA stenting can be done by retrograde or antegrade approach depending upon the anatomy of the duct.¹⁶ A preliminary angiogram is obtained to assess ductal anatomy.

The duct is crossed by appropriate wire (0.014" coronary wire) and premounted coronary stents is advanced over the wire (Figs 16A to D). Once satisfactory position is acquired (both the pulmonary and the aortic ends of the ductus are covered) the stent is deployed by inflating the balloon to appropriate recommended pressure.

Figs 14A and B: Procedure²: The coarctation and adjacent aorta are defined by quantitative angiography. A balloon of the same diameter as the narrowest aortic diameter adjacent to the coarctation is prepared. A "J" or curved-tip stiff guidewire is positioned retrogradely through the coarctation, around the aortic arch, and into the aortic root or occasionally into the right innominate artery. The dilation balloon catheter is passed over the wire and across the area of coarctation. When the balloon is centered, balloon is inflated several times until the waist in the balloon or the gradient disappears

Figs 15A to D: Angiographic pictures of stent insertion for re-coarctation following surgical repair; (A) preprocedure, (B) stent insertion, (C) stent expansion by inflation of internal balloon, (D) final result

Figs 16A to D: (A) LAO-cranial projection—ductus arteriosus in PA-IVS with severe hypoplasia of the RV. Proximal origin of ductus, (B) The tip of a cut pigtail is engaged in the ductal ampulla, (C) Balloon-stent positioned along ductal length ready for expansion, (D) fully expanded stent

Complications^{1,16}

Femoral vessel injury or occlusion, stent thrombosis, ductal spasm, ductus perforation or occlusion, stent migration, early restenosis.

Balloon Mitral Valvotomy

Mitral valve stenosis in children can be either rheumatic or congenital. Although rheumatic mitral valve stenosis is commonly due to the development of thickened mitral leaflets and fused commissures, congenital mitral stenosis encompasses a broad spectrum of anatomic variants, including the “typical” variant with thickened leaflets, shortened chordae, and decreased interchordal spaces, parachute mitral valve; and the hypoplastic mitral valve associated with HLHS.¹ This procedure was extended to

patients with congenital mitral valve stenosis.¹⁷ Though the incidence of rheumatic heart disease is decreasing significantly, we still have a major burden of juvenile mitral stenosis in India. The commonest used balloon is Inoue balloon (Toray International America). Because surgical repair of congenital mitral valve stenosis in infants and young children has high mortality and morbidity, the less invasive transcatheter technique remains a reasonable alternative, although the results remain variable, in part because of the varied morphology of the mitral valve stenosis.¹⁷ In general, balloon dilation is more favorable in those variants of mitral stenosis with commissural fusion and more balanced chordal attachments, and worse outcome is seen with parachute mitral valves, supramitral rings, or small mitral annulus; in younger patients; and in those who develop significant mitral regurgitation.¹⁸

RECOMMENDATIONS FOR MITRAL VALVULOPLASTY¹

- Symptomatic patients with moderate to severe isolated rheumatic mitral stenosis or asymptomatic patients with moderate to severe rheumatic mitral valve stenosis/restenosis associated with pulmonary hypertension.
- Symptomatic children >5 years of age with congenital mitral stenosis or restenosis who have mitral valve morphology that is favorable for balloon valvuloplasty.
- It can be considered for patients <5 years of age with congenital mitral valve stenosis with moderate to severe residual stenosis or with valve restenosis who have already undergone surgical valvuloplasty.

Complications¹

Iatrogenic mitral regurgitation, atrial or ventricular perforation, transient rhythm abnormalities, stroke, and femoral artery or vein trauma.

TRANSCATHETER OCCLUSION OF OTHER VASCULAR ABNORMALITIES**Coronary AV Fistula**

Coronary fistulae may arise from the right or left coronary artery and drain most commonly into the right atrium, ventricle, or pulmonary artery. Most patients are asymptomatic, and spontaneous regression has been reported.¹⁹ They can be symptomatic due to large left to right shunt in few cases and symptoms of coronary steal in others. In the adult population, the frequency of symptoms increases. Thrombosis within the fistula is rare but may cause acute myocardial infarction, paroxysmal atrial fibrillation, and ventricular arrhythmias.¹

Embolization can be performed with coils or other occluding devices.²⁰ Incomplete occlusion with residual shunting, myocardial ischemia due to inadvertent distal coronary artery occlusion are the important complications.¹

Pulmonary Arteriovenous Malformations

Pulmonary arteriovenous malformations (PAVMs) are abnormal direct connections between the pulmonary arteries and veins (bypassing the capillaries). Although uncommon, they may be life-threatening. PAVMs may be congenital and isolated or associated with liver disease, palliated CHD (in which no hepatic flow travels through the lung), cancer, or trauma. There is a strong association between PAVMs and Osler-Weber-Rendu syndrome. Manifestations of PAVMs include cyanosis (most commonly), paradoxical embolization, brain abscess, and rupture. Coil embolization of pulmonary arteriovenous malformations is effective in reducing right-to-left anatomic shunt fraction and in

improving arterial oxygenation.¹ It is well tolerated with low complication rate.²¹

TRANSCATHETER CLOSURE OF RUPTURED SINUS OF VALSALVA

Ruptured aneurysm of the sinus of Valsalva has is a very rare cardiac lesion. Majority of the aneurysms of sinus of Valsalva arise from the right coronary sinus and rupture into right ventricle.² Till now surgical repair was the only option for repairing these aneurysms, but recently there are attempts to close these fistulae by transcatheter closures. Various devices are used to close these fistulae effectively. Transcatheter procedures involve relatively low risks but need lot of technical expertise.

Clinical Examination: A Forgotten Art

YK Ambdekar

Over the last several years, medical science has rapidly marched forwards not only in the field of therapeutics but also in the field of diagnostics. But somewhere along the way, art of clinical examination has been left behind. Physicians in older generation practiced medicine without much diagnostic aids and had inevitably mastered art of clinical examination. Modern physician has an “exposure” to lots of “aids.” Easy availability of plethora of diagnostic tools has made the modern physician feel that clinical examination is superfluous for accurate diagnosis. However, in the absence of provisional diagnosis made on sound analysis of history and detailed structured physical examination, indiscriminate use of laboratory tests and polytherapy can be expensive and dangerous for the patient and disastrous for the community. Therefore, scientific advances are intended to facilitate and not eliminate the process of history taking and physical examination. Art of clinical examination must include ability to analyze information obtained through detailed history and abnormal findings on physical examination.

PURPOSE OF CLINICAL EXAMINATION

Detailed history taking and structured physical examination is a prerequisite of provisional diagnosis. It helps to select specific laboratory tests and plan rational therapy. It is ideal to analyze history to a point that it should help anticipate abnormal physical findings and then try to match results of physical examination. In case of discrepancy between anticipated and actual physical examination findings, one may have to cross check both history and physical examination. This becomes a self-learning exercise. It builds confidence and promotes transparency in medical practice.

DETAILED HISTORY TAKING

History taking should start with age of the patient as similar complaints at different age may connote varying

probabilities. Chief complaint has its own significance. Fever, pain in abdomen and vomiting may be common triad of symptoms in hepatitis, appendicitis and viral influenza. However, vomiting may be a chief complaint in hepatitis, abdominal pain in appendicitis and fever in influenza. Origin, duration and progress can add adjectives such as acute or subacute onset, short or long duration of symptoms and improving, worsening or stable progress that may narrow down the probable etiology of disease. Past history of similar disease points to recurrent diseases such as hyper-reactive airway disease or asthma or epilepsy. Every major illness in the past must be made note of as some of the diseases may present with varying forms of manifestations though related to the same disease. Systemic lupus erythematosus may present sequentially with apparently different organ involvement and a child presenting with renal disease but has a past history of skin rash, arthritis and mouth ulcers may point to varying manifestations at different times of the same disease. Family history helps to consider hereditary disorders. Personal history at times would offer clue to the diagnosis and often not volunteered by parents unless specially enquired by the physician. A child suffering from diabetes may present to the physician with fatigue and general weakness or coma and unless asked for, polyuria, polydipsia and polyphagia are often overlooked with resultant missing of diagnosis. Nutritional history is relevant in pediatric practice as many diseases are accompanied with nutritional deficiency and total care demands advice on proper nutrition irrespective of primary disease for which child may have presented. Birth history and developmental history are important especially in infants and young children. Birth events may have direct relation to the presenting disease. Developmental history helps to pick up subtle abnormalities such as mild developmental delay or autism and attention deficit disorder or learning disability. Socioeconomic

history contributes to understanding of diseases that may be the result of adverse socioeconomic status. It is important to realize that even the complicated problems are better solved by detailed history taking and proper analysis. Besides there are diseases that would be totally missed if one did not take into account analysis of history.

STRUCTURED PHYSICAL EXAMINATION

There cannot be a short cut to physical examination. Each part of physical examination is important and may offer a clue to proper diagnosis. Every physician must follow systematic pattern of physical examination, more so if diagnosis is elusive. However, due importance may not be given to some parts of physical examination and they would be emphasized in the following discussion. Unless every abnormal finding is noted correctly and analyzed properly, correct diagnosis may not be possible.

GENERAL EXAMINATION

It begins with description of “first look” of the patient with adjectives such as healthy, comfortable, acutely sick, chronically sick, anxious, breathless, confused, drowsy, etc. “First look” guides immediate plan of action. Anthropometric measurement and nutritional assessment is the integral part of physical examination in pediatric patients. It offers clue to the acuity or chronicity of the problem. Often hidden problems like chronic infection or organ dysfunction can be picked up by these measurements. Growth charts serve great purpose and must be maintained throughout childhood till adulthood. Developmental assessment is another important part of physical examination and basic screening tests can bring forth issues that parents may not have noticed or complained of subtle behavior changes or delayed language development may be the only pointer to learning disorder that must be picked up early in childhood for better outcome. Vital parameters such as pulse, respiratory rate and temperature must be noted with precision as in normal health they are maintained in a balanced proportion. Disproportionate increase in pulse and respiratory rate may suggest systemic inflammatory response and may warn against impending shock. Differential body temperature (central and peripheral temperature or core and skin temperature) and capillary refill time. Marked increase in pulse rate as compared to respiratory rate may point to primary cardiac problem as against marked increase in respiratory rate compared to pulse rate may be due to primary respiratory disorder. Such simple observations should not be missed. Unless special efforts are made to examine skin for any rash, it is easily missed. Purpuric rash of meningococcemia if not noted may prove to be a fatal mistake. Edema of feet may have to be looked for with care as it could be easily missed in early stages. Neck should be specially examined for engorged veins, as they are not noticed by cursory examination. Pallor is best

evaluated on ventral surface of the palm. Mild cyanosis may be difficult to appreciate unless carefully looked for and so also icterus.

In a neonate, physical examination should specially focus on cataract, cleft palate, congenital dislocation of hip, coarctation of aorta, lumbosacral spine and genitalia as these abnormalities are likely to be easily overlooked.

Systemic Examination

It should follow uniform pattern of inspection, palpation, percussion and auscultation. It is only when all these maneuvers are properly carried out and analyzed together that proper diagnosis may be achieved as many abnormal findings are shared by different pathologies. Following discussion will emphasize issues that may be routinely ignored.

Respiratory System

Sound produced during respiration suggests anatomy and pathology of the disease. Stridor indicates upper airway inspiratory obstruction; wheeze denotes lower airway expiratory obstruction and grunt is an attempt to increase end-expiratory pressure to prevent alveolar collapse (natural PEEP) as in pneumonia. Chest retraction suggests respiratory distress. Isolated suprasternal retraction indicates extrathoracic upper airway inspiratory obstruction. Isolated subcostal retraction denotes lower airway expiratory obstruction. Generalized intercostal retraction is seen in alveolar diseases. Severity and extent of chest retraction is proportionate to the severity of the disease. Chest retractions may be observed in a malnourished infant due to compliant chest wall even without any respiratory disease. Tachypnea needs cautious interpretation. When present in respiratory or cardiac disease, it is often accompanied with respiratory distress. Tachypnea without respiratory distress suggests metabolic acidosis. Deep and rapid respiration without any abnormal findings on physical examination of chest favors such a possibility. Loss of voice with tachypnea (silent tachypnea) indicates respiratory muscle paralysis and is easily mistaken for pulmonary or cardiac disease.

Abnormal chest findings should be analyzed by their distribution as it helps to localize the disease to lung, pleura or mediastinum. This is depicted as lobar, pleural or nonlobar nonpleural distribution. Disease affecting upper lobe of the lung results in abnormal physical signs restricted to upper half of the chest anteriorly, middle lobe affection to the lower-half of chest anteriorly and lower lobe involvement to mainly posterior part of the chest (as in lobar pneumonia). Abnormal findings are not restricted to lobar pattern in pleural disease, but are found anteriorly, laterally and posteriorly below a particular intercostal space (as in pleural effusion). However, physical findings in small pleural effusion may be restricted to few lower

intercostal spaces posteriorly. Abnormal chest signs not restricted to either lobar or pleural pattern may suggest mediastinal disease as in case of mediastinal space occupying lesion.

Hepatobiliary System

Anatomically four components need consideration for proper diagnosis—liver cell parenchyma, biliary tract, venous channels and reticuloendothelial cells. Each of these sites present with characteristic findings though there may be an overlap.

Hallmark of liver disease is enlarged liver. Liver size is better judged by liver span rather than extent of palpability of liver below the costal margin. Normal liver is of soft consistency while pathological enlarged liver is firm or hard. Enlarged soft liver is unusual and may suggest “pushed down” liver, in which case liver span is normal. Impalpable shrunk liver due to end stage liver disease is rare in pediatric patients. Normal liver has an edge, which is well defined but not sharp. Sharp edge denotes cirrhosis and rounded edge fatty liver.

Careful palpation of spleen is essential as it may add information in liver disease and so also detection of free fluid in peritoneal cavity—ascites.

Hepatomegaly, splenomegaly and ascites may be present in varying combinations.

All three signs indicate cirrhosis with portal hypertension and liver cell failure. Hepatosplenomegaly without ascites suggests either storage disorder or infection induced reticuloendothelial hyperplasia. Hepatomegaly with ascites without splenomegaly indicates sinusoidal venous obstruction (when associated with liver cell dysfunction) or post-sinusoidal venous obstruction (with normal liver function). Isolated splenomegaly may be a pointer to extrahepatic portal hypertension.

It is important to examine neck veins in every case of enlarged liver as disease like constrictive pericarditis may be easily mistaken for cirrhosis but for the presence of engorged neck veins.

Neurological System

Observation and play techniques are essential means of monitoring intellectual, behavioral and motor functions, especially in infants and young children. Beyond 4 to 5 years of age, neurological examination is more conventional and routine.

Gross motor functions are easily screened by simple maneuvers such as hopping on each foot, tandem walking forwards and backwards, toe and heel walk. Thereafter child should be asked to stand with his feet together, eyes closed and hands outstretched. This allows simultaneous assessment of abnormal movements and Romberg sign. Finger-nose test adds further information. Observing gait offers important information as it helps to localize the

disease to upper motor neuron, extrapyramidal system or peripheral lesion such as anterior horn, nerve or muscle.

Special attention is necessary to spine, skull, signs of meningeal irritation and increased intracranial pressure, papillary dysfunction, autonomic nervous system (vasomotor changes, blood pressure and temperature changes) and pattern of respiration.

Abnormal movements may be classified by the pattern as slow (dystonia, athetosis), rapid and jerky (tics, chorea) or rhythmic oscillatory (tremors, myoclonus).

Developmental reflexes are patterned responses that help assessment of general development of nervous system in first two years of life. Most of these reflexes appear at birth and disappear at sometime in first year. They include truncal incurvation, rooting, moro, palmer and plantar grasp, tonic neck reflex. However, few of them are not present at birth such as parachute and Landau reflex. They appear late in infancy, while Landau reflex disappears by 2 years of age, parachute reflex persists for life. Abnormality in developmental reflexes may be in the form of continued presence of a reflex that should have disappeared, absence of expected response or asymmetrical response. Usually they do not signify any localizing value.

Developmental assessment is an integral part of neurological examination. Parental concern about development needs to be addressed seriously as it often represents genuine abnormality. Language assessment is very important. If child does not attain first word by 18 months of age, detailed evaluation is necessary that should include hearing assessment, global brain function and behavioral assessment. Spectrum of autism, attention deficit hyperactivity disorder, pervasive developmental disorder and learning disability are easily missed unless suspected and evaluated properly.

Visual impairment must be differentiated from visual inattention. Roving eye movements and nystagmus suggest visual impairment.

Cardiovascular System

With easy availability of echocardiography, clinical examination is often ignored. However, unless clinical examination suspects heart disease, echocardiogram may not be asked for and hence it is equally relevant to master the art of clinical examination of cardiovascular system. While obvious abnormal findings may not be missed, it is important to focus attention on subtle signs that may be easily overlooked.

Soft short systolic murmur of ASD is often missed unless looked for carefully. Palpation of peripheral pulses can pick up coarctation of aorta or aortoarteritis. In fact pulse, blood pressure and neck veins offer lots of information along with inspection and palpation of precordium. Auscultation of heart may be confusing especially in case

of tachycardia but other clinical findings may predict auscultatory abnormalities.

Neonatal cardiac examination is tricky as “abnormal” findings may be transient while on the other hand, abnormality may appear later. Ideally, persistence of single second pulmonary heart sound beyond days 3 to 4 may suggest pulmonary outflow obstructive lesions that may be apparent after few weeks. Similarly, persistence of parasternal heave indicating right ventricular hypertrophy may signify congenital heart defect with right heart predominance.

Musculoskeletal System

Rheumatological diseases demand careful examination of joints. Early mild involvement may be evident only by performing different maneuvers to demonstrate restriction of extreme movements. Examination of spine and temporomandibular joints is as important; so also site of insertion of tendons. There are several accompanying physical findings that must be looked for and they include skin rash, mouth ulcers, alopecia, eye findings and involvement of skeletal muscles. Renal involvement in particular is of

paramount importance for proper management and may be picked up by periorbital edema that may have to be specially looked for.

Other Systems

Renal, hematological and endocrinal diseases offer clue in general examination. Edema and blood pressure may point out to renal disease, pallor with or without hepatosplenomegaly and bleeding manifestations signify hematological disorder and growth parameters and examination of genitalia and sexual maturity rating would help in diagnosing endocrinal disease. Gastrointestinal diseases present with nonspecific physical findings such as abdominal distension or tenderness that need careful evaluation.

In conclusion, there is a need to revive the art of clinical examination. Detailed history taking and physical examination should be followed with analysis of observed facts. Laboratory tests are no substitute to clinical examination and taken into account without correlation may misguide the physician. Empirical therapy without provisional diagnosis may result in harm to the patient and physicians must revive the forgotten art of clinical examination.

Rational Drug Therapy

Vikas Dua, Satya Prakash Yadav, Anupam Sachdeva

Irrational use of medicines is a major problem world-wide. World Health Organization (WHO) estimates that more than half of all medicines are prescribed, dispensed or sold inappropriately, and that half of all patients fail to take them correctly. The overuse, underuse or misuse of medicines results in wastage of scarce resources and widespread health hazards. Examples of irrational use of medicines include: use of too many medicines per patient (“poly-pharmacy”); inappropriate use of antimicrobials, often in inadequate dosage, for non-bacterial infections; over-use of injections when oral formulations would be more appropriate; failure to prescribe in accordance with clinical guidelines; inappropriate self-medication, often of prescription—only medicines; nonadherence to dosing regimes. In both the developed and the developing world, medically inappropriate, ineffective and economically inefficient use of pharmaceuticals commonly occurs in health care facilities. The costs of such irrational drug use are enormous in terms of both scarce resources and the adverse clinical consequences of therapies that may have real risks but no objective benefits. Only through a thorough understanding of the existing patterns of therapy, the magnitude of the ways in which such therapy departs from optimal practice, and the factors (clinical, psychological, political, economic, and cultural) which underlie them can an attempt be made to improve the quality and efficiency of drug therapy.

PROBLEMS OF IRRATIONAL DRUG USE

Background

Medically inappropriate, ineffective, and economically inefficient use of pharmaceuticals is commonly observed in the health care system throughout the world especially in the developing countries. However, various forms of inappropriate prescribing often remain unnoticed by

those who are involved in health sector decision-making or delivery of health services. This problem will usually come to the attention of health decision-makers or managers when there is an acute shortage of pharmaceutical budget and action for cost efficiency is required.¹

The need for promoting appropriate use of drugs in the health care system is not only because of the financial reasons with which policy makers and managers are usually most concerned. Appropriate use of drugs is also one essential element in achieving quality of health and medical care for patients and the community. Obviously, this should also become the concern of practitioners. Actions or intervention programs to promote the appropriate use of drugs should, therefore, be continuously implemented and systematically incorporated as an integral part of the health care system.²

Defining Rational Use of Drugs

The terms “appropriate” and “rational” use of drugs will be used interchangeably throughout the chapter. What is rational use of drugs? What does rational mean? People may have different perceptions and meanings regarding rational use of drugs, or more specifically regarding rational prescribing. However, the Conference of Experts on the Rational Use of Drugs, convened by the World Health Organization in Nairobi in 1985 defined that

“Rational use of drugs requires that patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements for an adequate period of time, and the lowest cost to them and their community”³

This is very much a medical model definition.

These requirements will be fulfilled if the process of prescribing is appropriately followed. This will include steps in defining patient’s problems (or diagnosis); in defining effective and safe treatments (drugs and non-drugs); in selecting appropriate drugs, dosage and duration; in

writing a prescription; in giving patients adequate information; and in planning to evaluate treatment responses.

The definition implies that rational use of drugs, especially rational prescribing should meet certain criteria as follows:³

- *Appropriate indication:* The decision to prescribe drug(s) is entirely based on medical rationale and that drug therapy is an effective and safe treatment.
- *Appropriate drug:* The selection of drugs is based on efficacy, safety, suitability and cost considerations.
- *Appropriate patient:* No contraindications exist and the likelihood of adverse reactions is minimal, and the drug is acceptable to the patient.
- *Appropriate information:* Patients should be provided with relevant, accurate, important and clear information regarding his or her condition and the medication(s) that are prescribed.
- *Appropriate monitoring:* The anticipated and unexpected effects of medications should be appropriately monitored.

Unfortunately, in the real world, prescribing patterns do not always conform to these criteria and can be classified as inappropriate or irrational prescribing. Irrational prescribing may be regarded as “pathological” prescribing, where the above-mentioned criteria are not fulfilled. Common patterns of irrational prescribing, may, therefore be manifested in the following forms:

- The use of drugs when no drug therapy is indicated, e.g. antibiotics for viral upper respiratory infections.
- The use of the wrong drug for a specific condition requiring drug therapy, e.g. tetracycline in childhood diarrhea requiring oral rehydration solution (ORS).
- The use of drugs with doubtful/unproven efficacy, e.g. the use of antimotility agents in acute diarrhea.
- The use of drugs of uncertain safety status, e.g. use of dipyrrone (Baralgan, etc.).
- Failure to provide available, safe, and effective drugs, e.g. failure to vaccinate against measles or tetanus, failure to prescribe ORS for acute diarrhea.
- The use of correct drugs with incorrect administration, dosages, and duration, e.g. the use of IV metronidazole when suppositories or oral formulations would be appropriate.
- The use of unnecessarily expensive drugs, e.g. the use of a third generation, broad-spectrum antimicrobial when a first line, narrow spectrum, agent is indicated.

Some examples of commonly encountered inappropriate prescribing practices in many health care settings include:

- Overuse of antibiotics and antidiarrheals for non-specific childhood diarrhea.
- Indiscriminate use of injections, e.g. in malaria treatment.
- Multiple drug prescriptions.
- Excessive use of antibiotics for treating minor acute respiratory infection (ARI).

- Minerals and tonics for malnutrition.
- Consumers may have a very different perspective as to what is rational.

The drug use system is complex and varies from country to country. Drugs may be imported or manufactured locally. The drugs may be used in hospitals or health centers, by private practitioners and often in a pharmacy or drug shop where over the counter (OTC) preparations are sold. In some countries all drugs are available over available over the counter! Finally, the public includes a very wide range of people with differing knowledge, beliefs and attitudes about medicines.

Monitoring the Use of Medicines

From 1990 to date, the World Health Organization (WHO) has created a database of more than 700 published and unpublished surveys of medicine use carried out in developing countries and countries with economies in transition. Results from this database were initially presented at the second International Conference on Improving the Use of Medicines (ICIUM) that took place in Thailand in 2004.³ Some updated results from this database indicate that the use of medicines has remained much the same, slightly increasing over the last 15 years. The results further indicate that in Africa, Asia and Latin America, only about 40 percent of all patients were treated in accordance with clinical guidelines.

Factors Underlying Irrational Use of Drugs

There are many different factors which affect the irrational use of drugs. In addition, different cultures view drugs in different ways, and this can affect the way drugs are used.

The major forces can be categorized as those deriving from patients, prescribers, the workplace, the supply system including industry influences, regulation, drug information and misinformation, and combinations of these factors:³

- Patients
 - Drug misinformation
 - Misleading beliefs
 - Patient demands/expectations
- Prescribers
 - Lack of education and training
 - Inappropriate role models
 - Lack of objective drug information
 - Generalization of limited experience
 - Misleading beliefs about drugs efficacy
- Workplace
 - Heavy patient load
 - Pressure to prescribe
 - Lack of adequate lab capacity
 - Insufficient staffing
- Drug supply system
 - Unreliable suppliers

- Drug shortages
- Expired drugs supplied
- Drug regulation
 - Non-essential drugs available
 - Non-formal prescribers
 - Lack of regulation enforcement
- Industry
 - Promotional activities
 - Misleading claims

All of these factors are affected by changes in national and global practices. For example, the frequent use of injections is declining in many African countries because of the fear of AIDS. In some countries, however, the use of injectibles remains high due to false assumption of prescribers that injections will improve patient satisfaction and that they are always expected by the patients.

Impact of Inappropriate Use of Drugs

The impact of this irrational use of drugs can be seen in many ways:

- Reduction in the quality of drug therapy leading to increased morbidity and mortality.
- Waste of resources leading to reduced availability of other vital drugs and increased costs.
- Increased risk of unwanted effects such as adverse drug reactions and the emergence of drug resistance, e.g. malaria or multiple drug resistant tuberculosis.
- Psychosocial impacts, such as when patients come to believe that there is “a pill for every ill”. This may cause an apparent increased demand for drugs.

Examples of Irrational Drug Use

There are various forms of irrational use of drugs. Drug use can be measured in general and also for specific diagnoses. The following examples illustrate the extent of problems of misuse and overuse in studies from around the world.

All Diseases

- *Polypharmacy*: The number of drugs per case or per episode describes the pattern of polypharmacy, where more than one drug is prescribed (often unnecessarily) for a

condition. In one study in Indonesia,⁴ the occurrence of polypharmacy or multiple prescribing was obvious, where the average number of drugs per case was 3.8 both for under fives and for the over five age group.

When the number of drugs per case was broken down by diagnosis, very little change was noted. The general pattern of polypharmacy occurs almost independent of diagnosis⁴ (Fig. 1).

- Antibiotic use is a common drug use indicator.⁴ Excessive antibiotic use leads to resistance (Fig. 2).
- Injection use is another simple indicator of therapeutic practices. In the study from Indonesia mentioned above, almost half of the under fives and more than 70 percent of the over five age group received at least one injection⁴ (Fig. 3).

When injection use was broken down by diagnoses, overuse was seen to be common for many illnesses. The reasons for the overuse of injections are complex. Prescribers tend to believe that patients expect and are satisfied by receiving injections. Some patients do ask for injections. However, many dislike injections but accept them because “the doctor knows best”. There appears to be great variation in attitudes toward injections across different societies⁴ (Figs 4 and 5).

Disease-specific Indicators

When drug use is studied for specific illnesses, useful insight can be gained.

Fig. 2: Drugs per case by diagnosis, Indonesia 1987

Fig. 1: Drugs per case by age group, Indonesia 1987

Fig. 3: Percentage of patients receiving antibiotics, Indonesia 1987

Fig. 4: Percent of patients receiving injections, Indonesia 1987

Drug Use in Acute Respiratory Infection

Many drugs, particularly antibiotics, are used to treat minor upper respiratory tract infections. A major portion of the cost of ARI treatment is due to excessive use of antibiotics⁴ (Fig. 6).

Incorrect Treatment of Malaria

In many African countries, malaria is treated with injectible chloroquine rather than adequate doses of oral chloroquine. This leads to apparent treatment failure, which in Ghana is called “go slow malaria”.

Poor Compliance with Tuberculosis Therapy

In many countries with tuberculosis programs, less than 50 percent of patients fully complete their course of therapy which may last for 6 to 8 months. This results in treatment failures and the emergence of multiple resistant organisms (MDRTB). To counteract this dangerous trend, WHO and the International Union against tuberculosis have popularized the use of Directly Observed Treatment Short course (DOTS).⁵ In this system, TB patients are directly supervised taking their medication. When this is done, cure rates of over 90 percent are possible. However, effectiveness has varied widely across different environments.

Fig. 6: ARI treatment pattern, Indonesia 1987

Underuse of Effective Drugs

In both developed and developing countries, some conditions for which effective medicines exist are undertreated. Examples of these include hypertension, depression or anemia during pregnancy. These conditions can be life threatening and severely disabling. They are under diagnosed because they are not checked for regularly and health workers do not consider these conditions. However, these conditions are very amenable to therapy. Thus, failure to treat serious conditions is another form of irrational drug use.

Hospital Problems

Drug use in hospitals has been a neglected area. However in both developed and developing countries the misuse of antibiotics, particularly for surgical prophylaxis, has been widely reported. Hospitals have been able to improve antibiotic use through the use of formularies.

Fig. 5: Injection use by diagnosis, Indonesia 1987

Drug Use Patterns in Developing Countries

In order to encourage a standard approach to measuring problems in drug use, the International Network for the Rational Use of Drugs (INRUD) coordinated the development of standard drug use indicators and encouraged indicator studies in a number of developing countries during the period 1990-1992.⁶⁻⁹ These results are presented below:

The average number of drugs prescribed in public sector facilities in most of these countries ranges from 1.3 to 2 drugs. However, Indonesia, Nigeria and Ghana differ

significantly from this average. The use of generics varies from 37 to 94 percent. This tends to depend on government regulations and the enforcement efforts in the country (Fig. 7).

Antibiotics are commonly used in developing countries due to the high load of infection. Most countries tend to lie in the range of 25 to 40 percent, though some are considerably higher (Fig. 8).

The use of injections varies considerably, and seems to be declining in many countries. The use of injections is also affected by the availability of injectable drugs and

Fig. 7: Average number of drugs per patient, 1990-1992

Fig. 8: Percent prescribed as generics, 1990-1992

Fig. 9: Percent receiving antibiotics, 1990-1992

Fig. 10: Percent receiving injections, 1990-1992

syringes and needles. However, rates as high as 48 percent, as occurred in Uganda in September 1990, are clearly too high, particularly in the HIV/AIDS era (Fig. 9).

Percentage receiving injections, 1990-1992 is shown in (Fig. 10).

Patient Care Indicators

More recently efforts have been made to quantify the consulting and dispensing process. The consultation time in most country studies varies from 2.3 to 3.5 minutes.

The events occurring during this time frequently do not include physical examinations.

Dispensing has been observed in a limited number of countries. The average times vary from 12 to 86 seconds, which is a short time to convey what may be complex information about prescribed drugs to the patient (Fig. 11).

When patients are assessed as to their knowledge of how they should take drugs, between 27 and 83 percent know how and when to take their drugs. Potentially, this could result in major misuse of drugs (Fig. 12).

Fig. 11: Average consultation time, 1990-1992

Fig. 13: Percent patients knowing drug dosing, 1990-1992

Fig. 12: Average dispensing time, 1990-1992

Fig. 14: Percent of key drugs in stock, 1990-1992

Percent patients knowing drug dosing, 1990-1992 is shown in (Fig. 13).

Facility Indicators

Drug treatment may vary according to the availability of drugs. In a series of surveys of the availability of 10 to 15 key drugs, the drugs were available between 60 and 90 percent of the time, except in Ecuador. These data from different countries reflects the present situation in prescribing (Fig. 14).

DECISION MAKING FOR RATIONAL USE INTERVENTIONS

Introduction

Once a determination has been made that a drug use problem exists in an institution, an area, or a country, action to remedy the problem usually follows. Unfortunately, it is not always clear what intervention will be most effective. To decide which intervention(s) should be undertaken, preliminary work is required.

First, the drug use problem should be clearly defined. After this, the various motivating factors should be

identified and assessed. Then comes the stage of listing interventions. There are usually multiple options for dealing with any specific problem. Once these possibilities have been listed, the difficult task of choosing one or two interventions should occur. When more than one intervention is selected, each should be of a different type (regulatory, managerial, or educational).

When the intervention is undertaken it is important that there be a control group and that the sample sizes are adequate to detect differences if they exist. Once the control study has been undertaken, the results should be assessed and follow-up decided. Three outcomes are likely. First, the intervention may be ineffective and should be dropped; second, the intervention might require revision and restudy; third, in a few cases the intervention may be clearly effective, and such interventions can then be translated into national programs.

Choosing Strategies to Test and Implement

You might find that, in addition to the above techniques, there are other managerial and regulatory strategies that could be considered for your country or your program. It is important to choose a small number of strategies likely

to succeed, test them on a pilot basis, and then to implement the strategy as effectively as possible.

The following factors should be considered in choosing strategies:¹⁰⁻¹²

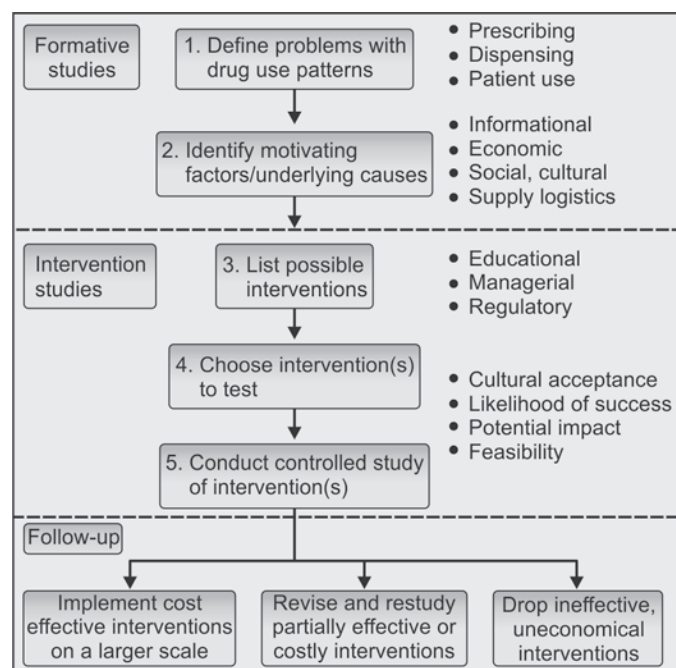

- *Expected magnitude of impact*: If the strategy is successful, what is the likely impact? That is, will it affect only a few drugs, only a few providers, or only save a small amount of money? Or will the impact be great? Obviously, preference goes to strategies likely to have greater impact on priority drug use problems.
- *Likelihood of success*: All things considered, how likely is success? Will opposition be so great or the task so complex that success is unlikely?
- *Unintended effect*: What are the unintended effects that might occur? How can these effects, if any, be minimized?
- *Political and cultural feasibility*: How acceptable is the strategy in the local context? Will political and cultural factors favor development and implementation of the strategy, or will they severely hinder it?
- *Technical feasibility*: What are the technical requirements of the strategy? Computers? A highly developed information system? How much technical help (people, systems, equipment) will be needed?
- *Cost (economic feasibility)*: What is the cost, particularly compared to available resources and to the potential benefits of successfully implementing the strategy?
- *Potential for donor support*: Will donor support be needed? Requested? How likely is it that the donors with whom you work will support the proposed approaches?

If an informal review of possible strategies has reduced the number to relatively few (perhaps two to eight), then a decision matrix could be made using the alternative strategies as one dimension and the above six selection factors as the other dimension. Whatever strategies are chosen, they should be tested in advance wherever possible and the impact of their implementation should be carefully monitored.

Stages in Attacking a Drug Use Problem¹³ (Flow chart 1)

- The initial action required is to characterize the drug use situation with a general drug use indicator study (*quantitative*).
- The problem may require clarification which can be done through follow-up *quantitative* studies (disease specific or level specific).
- Following this stage it is essential that the motivations of prescribers and the constraints within the system are investigated. This requires *qualitative* studies.
- With the available data you can then identify the key factors to change. This requires synthesis of data

Flow chart 1: Framework for formative and intervention studies

and prioritization of problems. Are they: important, changeable, feasible?

- Intervention selection should ensure that they are targeted to identified factors and constraints.
- Study design should take into account the available resources both financial and human and the administrative structure.
- Monitor progress of the intervention closely as unexpected changes may complicate the result of the intervention.
- Evaluate the results carefully, obtaining assistance in data analysis if necessary.
- Feedback the results of the intervention (positive or negative).

WHO Advocates 12 Key Interventions to Promote More Rational Use¹⁴

- Establishment of a multidisciplinary national body to coordinate policies on medicine use.
- Use of clinical guidelines.
- Development and use of national essential medicines list.
- Establishment of drug and therapeutics committees in districts and hospitals.
- Inclusion of problem based pharmacotherapy training in undergraduate curricula.
- Continuing in service medical education as a licensure requirement.
- Supervision, audit and feedback.
- Use of independent information on medicines.

- Public education about medicine.
- Avoidance of perverse financial incentives.
- Use of appropriate and enforced regulation.
- Sufficient government expenditure to ensure availability of medicines and staff.

A Mandated Multi-Disciplinary National Body to Coordinate Medicine Use Policies

Many societal and health system factors, as well as professionals contribute to how medicines are used. Therefore, a multi-disciplinary approach is needed to develop, implement and evaluate interventions to promote more rational use of medicines. A national regulatory authority (RA) is the agency that develops and implements most of the legislation and regulation on pharmaceuticals. However, ensuring rational use requires coordination with other stakeholders in more activities than those normally covered by RA's. Thus a national body is needed to coordinate policy and strategies at national level, in both the public and private sectors. The form this body takes may vary with the country, but in all cases it should involve government (ministry of health), the health professions, academia, the RA, pharmaceutical industry, consumer groups and non-governmental organizations involved in health care. The impact on medicine use is better if many interventions are implemented together in a coordinated way, single interventions often having little impact.

Clinical Guidelines

Clinical guidelines (standard treatment guidelines, prescribing policies) consist of systematically developed statements to help prescribers make decisions about appropriate treatments for specific clinical conditions. Evidence-based clinical guidelines are critical to promoting rational use of medicines. Firstly, they provide a benchmark of satisfactory diagnosis and treatment against which a comparison of actual treatments can be made. Secondly, they are a proven way to promote more rational use of medicines provided they are:

- Developed in a participatory way involving end-users;
- Easy to read;
- Introduced with an official launch, training and wide dissemination;
- Reinforced by prescription audit and feedback.

Essential Medicines List Based on Treatments of Choice

Essential medicines are those that satisfy the priority health care needs of the population. The use of an essential medicines list (EML) makes medicine management easier in all respects. Procurement, storage and distribution are easier to do with fewer items, and prescribing and dispensing are easier for professionals as they have to know about fewer items. A national EML should be based

upon national clinical guidelines and should be the focus for government activities in the public sector, e.g. procurement, distribution, insurance reimbursement policies and training. Only health workers who are approved to use certain medicines should be supplied with them. Medicine selection should be done in a transparent way by a central committee with an agreed membership and using explicit, previously agreed criteria, based on efficacy, safety, quality, cost (which will vary locally) and cost-effectiveness.

Drugs and Therapeutics Committees in Districts and Hospitals

A drugs and therapeutics committee (DTC) is a committee designated to ensure the safe and effective use of medicines in the facility or area under its jurisdiction. Such committees are well established in industrial countries as a successful way of promoting more rational, cost effective use of medicines in hospitals. Governments may encourage hospitals to have DTC's by making it an accreditation requirement to various professional societies. DTC members should represent the administration and all the major specialties in any given facility. The members should also be independent and declare any conflict of interest. A senior doctor would usually be the chairperson and the chief pharmacist, the secretary. Unfortunately many DTC's are procurement committees. Their activities should however be much broader and should include developing or adapting clinical guidelines, medicines selection, monitoring medicines use and taking corrective action, staff education, controlling drug promotional activities by pharmaceutical industry within the premises of the health facility and monitoring adverse drug reactions.

Problem-based Training in Pharmacotherapy in Undergraduate Curricula

The quality of basic training in pharmacotherapy for undergraduate medical and paramedical students can significantly influence future prescribing. Rational pharmacotherapy training, linked to clinical guidelines and essential medicines lists, can help to establish good prescribing habits. Training is more successful if it is problem based, concentrates on common clinical conditions, takes into account students' knowledge, attitudes and skills, and is targeted to the students' future prescribing requirements (WHO 1994).

Continuing In-service Medical Education as a Licensure Requirement

Continuing in-service medical education (CME) is a requirement for licensure of health professionals in many industrialized countries. In many developing countries opportunities for CME are limited. In these countries no incentives are offered for CME since it is not required for continued licensure. CME is likely to be more effective if it

is problem based, targeted, involves professional societies, universities and the ministry of health, and is face-to-face. Printed materials, such as bulletins or newsletters, that are unaccompanied by face to face interventions, have been found to be ineffective in changing prescribing behavior. CME should be provided for all cadres of health worker including in the informal sector such as drug retailers. Often due to lack of public funds CME is heavily supported by the pharmaceutical sector and may thus be biased. Governments should therefore support efforts by university departments and national professional associations to give independent CME.

Supervision, Audit and Feedback

Supervision is essential to ensure good quality of care. Supervision that is supportive, educational and face to face, will be more effective and better accepted by prescribers than simple inspection and punishment. Effective forms of supervision include prescription audit and feedback, peer review and group processes such as self monitoring. Many industrialized countries have a strong supervisory infrastructure but resources are often lacking for this in low-income countries.

Independent Information on Medicines

Inadequate knowledge and lack of access to independent information about medicines significantly contribute to irrational use of medicines. Often, the only information that practitioners receive is provided by the pharmaceutical industry and may be biased. Provision of independent (unbiased) information is therefore essential. Drug information centres (DIC's) and drug bulletins are two useful ways to disseminate such information. Both may be run by government or a university teaching hospital or a non-governmental organization, under the supervision of a trained health professional.

Public Education about Medicines

It is essential that the general public have the skills and knowledge to make informed decisions about when and how to use medicines, and to understand their potential risks as well as benefits. Without such knowledge and skills, people will often not get the expected clinical outcomes and may suffer adverse effects. This is true for prescribed medicines, as well as medicines used without the advice of health professionals.

Governments have a responsibility to ensure both the quality of medicines and the quality of the information about medicines available to consumers. This will require:

- Ensuring that over the counter medicines are sold with adequate labeling and instructions that are accurate, legible, and easily understood by lay persons;
- Monitoring and regulating advertising, which may adversely influence both prescribers and consumers;
- Running targeted public education campaigns, which take into account cultural beliefs and the influence of social factors.

Avoidance of Perverse Financial Incentives

Financial incentives that encourage irrational use of medicines should be avoided. For example, prescribers who earn money from the sale of medicines (e.g. dispensing doctors) prescribe more medicines, and more expensive medicines, than prescribers who do not. The health system should therefore be organized to deter prescribers who dispense or sell medicines. Patients prefer to get 2 to 3 medicines rather than one if the total cost to them is the same regardless of the number of medicines. Flat prescription fees covering all medicines in whatever quantities within one prescription lead to over prescription. User charges should therefore be made per medicine, not per prescription. Insurance policies should provide reimbursement only for essential medicines, not non-essential ones.

Appropriate and Enforced Regulation

Regulation of the activities of all actors involved in the use of medicines is critical to ensuring rational use. Regulations only have an effect if they are enforced, and the regulatory authority sufficiently funded and backed up by the judiciary.

Sufficient Government Expenditure to Ensure Availability of Medicines and Staff

Irrational drug use is caused in part by the lack of essential medicines and the lack of appropriately trained personnel. Without sufficient competent personnel and finances, it is impossible to carry out any of the core components of a national programme to promote rational use of medicines. Poor clinical outcome, needless suffering and economic waste are sufficient reasons for large government investment.

Rational Use of Medicines: National Strategy¹⁴

Ensure therapeutically sound and cost effective use of medicines by health professionals and consumers. Improving the use of medicines by health workers and the general public is crucial both to reducing morbidity and mortality from communicable and non-communicable diseases, and to containing drug expenditure.

Ideally, therapeutically sound and cost effective use of medicines by health professionals and consumers is achieved at all levels of the health system, and in both the public and the private sectors. A sound rational drug use program in any country has three elements:

- *Rational use of medicines strategy and monitoring:* Advocating rational medicines use, identifying and promoting successful strategies, and securing responsible medicines promotion.

- *Rational use of medicines by health professionals:* Working with countries to develop and update their treatment guidelines, national essential medicines lists and formularies, and supporting training programs on rational use of medicines.
- *Rational use of medicines by consumers:* Supporting the creation of effective systems of medicines information, and empowering consumers to take responsible decisions regarding their treatment.

The above elements are formulated in such a way as to reflect the main responsibilities of a national essential medicines program.

Rational medicine use strategy and monitoring: Need for implementation of a national strategy to promote rational use of medicines by health professionals and consumers and provision of monitoring.

Rational medicine use by health professionals: Develop national standard treatment guidelines, essential medicine lists, educational program and other effective mechanisms to promote rational medicine use by health professionals.

Rational medicine use by consumers: Establishing effective medicines information systems to provide independent and unbiased medicine information—including on traditional medicine—to the general public and to improve medicine use by consumers.

Drug selection while treatment must be based on the following:¹⁵

- *Relevance to disease:* Indicated in the treatment of prevalent diseases.
- *Efficacy and safety:* Based on the objective results from adequate pharmacological studies including at least expanded phase (II) clinical trials and/or additional phase (III) studies.
- *Quality*
- *Cost*—of treatment regime (not just the unit cost).
- *Appropriateness* to the capability of medical personnel at different levels of health care—The level of expertise required to prescribe, administer and monitor safety and adverse effects of single drug or group of drugs in the therapeutic category must be considered. Consideration should be given to the competence of local personnel in making the correct diagnosis.
- *Local health problems:* The influence of concomitant, locally prevalent diseases or conditions on pharmacokinetic and pharmacodynamic parameters modifying therapeutic response have to be considered in making the selection, e.g. malnutrition, liver disease.
- *Benefits/risk ratio:* When several comparable drugs are available for the same therapeutic indication it is necessary to select the one which provides the most favorable benefit/risk ratio.
- *Preferential factors* for evaluating therapeutically equivalent drugs: When two or more drugs are therapeutically equivalent preference should be given to:
 - The drug most thoroughly investigated and therefore the best understood with respect to its beneficial properties and limitations.
 - The drug which is clinically appropriate for more than one disease.
 - The drug with the most favorable pharmacokinetic properties, e.g. to improve the compliance to minimize risk.
 - The drug that are in a dosage form that is easy for the health staff to dispense easily and safely administer to the patient.
 - The drugs that are easy for the patient to take or with the broadest acceptability.
 - The drugs, pharmaceutical products and dosage forms with favorable stability under anticipated local conditions for which storage facilities exist.
 - The drugs for which reliable local manufacturing facilities exist.
- In the majority of cases the drugs should be formulated as single compounds. Fixed ratio combination are only acceptable when:
 - The clinical value of simultaneous use of more than one dose is documented.
 - The therapeutic benefit of the combination is greater than the sum of each of the individual components.
 - The combination is safer than the use of an individual drug.
 - The cost of the combination product is less than or equal to the total cost of the individual products.
 - The compliance is improved.
 - The combination must be such that sufficient quantities to meet the needs of the majority of the population can be maintained.
- *Periodic review of drug list:* Yearly or whenever necessary to incorporate significant new therapeutic advances and selected drugs.
 - Generally new drugs should be introduced only if they offer distinct advantages over previously selected drugs.
 - If on the basis of new information, drug already on the list are found to no longer possess a favorable benefit/risk ratio, they should be replaced by drugs with the higher benefit/risk ratio.
- *International non-proprietary names* (INN; generic names) should be used for drugs.

CONCLUSION

Drug use is the end of the therapeutic consultation. Ensuring that the correct drug is given to the correct patient is a high priority for all health professionals. Improving the rational use of drugs is a challenge that can only be achieved by carefully

testing interventions to identify what works. Reporting both positive and negative results is most important to build up a body of knowledge that can be used by others to make choices about their programs. Means exist to measure drug use, to intervene to change drug use, and to evaluate these interventions. Health planners and prescribers need to use these tools to improve the quality of care provided to their patients.

Modern Day Office Practice: Concepts and Critical Analysis

Devesh Aggarwal, Mahaveer Jain

A successful practice is about the doctor and patient succeeding together. There is no greater achievement for a doctor than a cured and satisfied patient. While the cure is totally dependent on our technical knowledge and its smooth execution, for which we are all well trained in the many years, we spend in the medical college, the satisfaction of the patient is a very different task. This is a skill which we all usually acquire after years of hard work but still sometimes find ourselves in a puzzling situation and often pondering.

“I have cured the patient in the best possible manner, why is he still so dissatisfied?”

A structured approach towards the patient goes a long way in helping us achieve our goal.

These factors are listed in Table 1.

DOCTOR’S ATTRIBUTES

Availability

Easy and ready access to the doctor is the cornerstone of any practice, this is the area of practice that the doctor has to manage very well, for otherwise everything else falls apart and nullifies all the efforts. To improve our accessibility to the patient we must keep a flexible schedule. While most of the patients can be seen during the normal office hours, we must also make room for our working patients. A chunk of our patients may find it difficult to leave their workplace during normal working hours. Such patients should be adjusted with early morning or late appointments to minimize attrition.

Behavior

Moods are infectious. A doctor with a “Happy Glow” is more likely to have a satisfied patient. A patient is likely to leave your chamber filled with satisfaction and with smiles if he is confident that you have listened to all his problems

with patience. You should appear patient, confident and in control of the whole situation. This way the patient leaves your office not just cured but happy also. If you have reached your clinic late, be sure to gracefully apologize to all the waiting patients before entering your chamber. Once in the chamber, as the patients enter your room greet everyone with a smile and direct them where to sit. Acknowledge everyone accompanying the patient so that they all feel involved in the visit. Make sure to establish an eye contact with the parents and the child, this helps in

Table 1: Factors which determine the success of an office practice

<i>Doctor attributes</i>	<ul style="list-style-type: none"> • Availability • Behavior • Competence • Communication skills • Attire • Managing referrals • Patience and good listener
<i>Office attributes</i>	<ul style="list-style-type: none"> • Location • Physical environment • Front desk • Trained manpower • Appointment management • Electronic health records • Mode of payment
<i>Patient attributes</i>	<ul style="list-style-type: none"> • Cultural and lifestyle diversity • Dissatisfied or angry • Language barrier • Faith and confidence

bonding. Avoid excessive stare-downs as this appears to be threatening and makes the patient uncomfortable. After finishing your job if you feel the patient may need a close watch or the parents are not fully satisfied while leaving the office, give the parents the permission to call you back in case they are in doubt about the child's condition or they find the progress unsatisfactory.

Competence

Years of rigorous training in the medical college has given us all the technical strength to practice. But, we must not forget that this is the age of information and knowledge. This is the age of internet and sizeable chunk of patients surf the net for their problems. We must keep ourselves abreast with the latest in our fields before the patient outgrows us. We must keep in touch with the latest literature (Journals and books), regularly attend CME's, plenty of websites, like those of Indian Pediatrics, AAP- Guidelines, WHO—Guidelines are available to guide and help us. In a difficult clinical situation do not be in a hurry to give the verdict. Refer to available resources and colleagues before taking a final decision.

Communication Skill

Do not forget the rule of the "Golden Minute". When the patient has entered your office and you have made him comfortable let him start with his history. Once the patient starts with his history do not interrupt him for at least the first minute. Doing so makes the patient feel that you are either not listening to all his problems and want to concentrate on only a few or that you are in a hurry and want him out quickly. While the patient is narrating his history, do maintain an eye contact. With lack of eye contact whether for history writing or for anything else, makes the patient feel that you are not listening anymore and already planning your treatment. This makes the patient unsure of the exactness of your prescription.

During conversation do make sure that the language of communication is to the patients and your comfort. Trying to use a language which is not comfortable for the patient is equivalent of non-communication. Your body movements should be slow and gentle. Rapid body movements convey hurry and aggression which no patient appreciates.

Attire

Contrary to what is popularly believed, children and patients appreciate their doctor in a white coat. A study from Dharwad, Karnataka¹ looked into the patient's perception as to what a doctor should wear. This included both urban and rural parents. Majority of the total assertive respondents preferred a formal traditional attire and appearance for the pediatrician. The respondents generally favored a white coat and nameplate on the

pediatrician, shoes and necktie for the male pediatrician and scarf for the female pediatrician. They did not approve clothes with jazzy designs, use of perfumes, long hair, T-shirts and jeans pants for the male pediatrician, chudidhar, lipstick and other make ups, costly jewellery and short hair for the female pediatrician. Similarly traits of nurse professionalism as perceived by the patient were highest in white uniform.

There is a lot of debate as to wearing of protective gear by the pediatrician to prevent themselves from infection. Unlike popular perception the use of face mask or face shield does not frighten the parents or the child (Figs 1A to D). However face shields may be a better option, as given a choice, both parents and children would prefer this.²

Managing Referrals

During our routine office practice we often need referral services. We should not hesitate from doing so. We must explain to the patient why we need the referral and must make a referral note for the referred physician detailing him about the patient and with the exact reason and requirements of the referrals. Instruct your front desk to assist the patient in fixing an appointment with the referred doctor. Insist on getting a feedback from the referred doctor and the patient to keep yourself in the loop of the entire medical management.

OFFICE ATTRIBUTES

Location

Those with an old established office practice realize the importance of the location of their office. When setting up a new practice the doctor must ensure that the location of the clinic does offer his clientele the advantage of easy

Figs 1A to D: Face mask and face shield for protection
(For color version see plate 18)

access. The downtown areas are sometimes so crowded that it is difficult for the patient to reach on time and often if he does so, he may face hardship in finding a parking space. This, however, may not be an important factor in an office practice where majority of the clientele is using a public transport. Similarly, the office should also not be uncomfortably away from the city. An ideal practice should be located midway of the two, to give the patients an easy and comfortable access.

Front Desk

This is where the action starts. It is the showcase of any practice. The front desk staff should always have a friendly and smiling face and have an attitude of “how a job can be done” and not “why it cannot be done”. The front desk should be an open desk where the patient should be directly able to see and speak with the staff. A desk which is closed in the front with a glass partition often fails to welcome the patients properly by acting as a barrier between them and the staff. Avoid using any excessive signages particularly if they sound authoritative (e.g. patients late for their appointment will be seen at last). Signages if any should be very neatly prepared on the computer and pasted in a plastic sleeve. This is cheap, aesthetically better and looks more professional. Cluttering on the front desk is an absolute no no, instruct and periodically check that the front desk staff is keeping the records and stationery well arranged on the counter and any eatables and beverages are not visible on the desk. Train the front desk staff that any conversation between them should be soft and not be loud enough for the waiting patients to hear. They should not indulge in conversations involving movies, TV shows, etc.

Physical Environment

Neatness is the key word. Depending on the kind of practice everything can vary but neatness cannot be compromised upon.

Basic important elements are:

- Clean and shining floor with no littering.
- Well placed furniture with no cuts exposing foam or any stuffing.
- Plants, if any, should be well maintained and not look neglected.
- Dustbin clearly visible to all patients.
- Easily accessible toilet.
- Television, if any, should be played softly and set to channels of children's interest. Strictly no filmy channels.
- Magazines should be carefully chosen and should relate to health issues, parenting, educational issues, etc. Avoid magazines concerning social or filmy gossip. These need to be periodically changed to discard old and messy magazines.

Trained Manpower

This is a great efficiency booster in a busy practice. A well-trained nursing staff may initially appear to be a financial burden but is very rewarding in a busy practice.

- A well-trained nurse can prime the patient that he/ she is the next to be seen.
- Help them arrange their documents beforehand, for many patients start looking for documents after coming into doctor's chamber.
- A well-trained nurse can do the anthropometry and plotting of growth charts.
- Trained nurse can often help the front desk during “Prime time Crisis”.

This way even a couple of minutes saved per patient will result in many more patients seen with greater efficiency during a day. This is both qualitative and quantitative enhancement to practice.

Appointment Management

To improve our accessibility to the patient we must understand our patient profile. Having a rigid appointment schedule can be patient unfriendly. While majority of the patients can be seen during main working hours,³ some patients find it difficult to leave their workplace during office hours. Such patients should be adjusted by either giving them early morning (Pre-Office) or week end appointments. This would decrease your patient attrition rate.

The appointments should be made out in such a manner, so as to place the clinic appointments as far apart as possible keeping ample space in between for patients with acute ailments.

Despite best planning, sometimes waiting does happen. If this happens because of your reaching late to the clinic a simple smile and an apology to the waiting patients usually offsets any resentment in the patient who has been waiting for you. In a study⁴ it was found that patients were OK with waiting time of 15–20 minutes but the satisfaction level dropped significantly with every minute spent in clinic after that (Fig. 2). If one is running late do not try to cut down on your consulting time per patient but try to reschedule the appointments. It has been seen that the more time spent in the consultation offsets patients dissatisfaction due to a longer waiting period (Fig. 3)

Due care needs to be taken of your patient needs while you are unavailable for personal reasons or during a vacation. These can be solved either by a group practices where your patients know whom to reach in case of your unavailability or with the help of an hospital attachment which offers round the clock coverage by a senior resident.

Website

A web-based appointment⁵ scheduling offers the patient a 24 X 7, service where he can book an appointment at

Fig. 2: Patient satisfaction and waiting time

Fig. 3: Physician care and waiting time

an hour of his choice. This reduces the load on the front desk which is already burdened with OPD register, card machines and waiting patients.

Electronic Health Records

Several pediatric softwares are available in the market and are frequently advertised in Indian Pediatrics journal. These are useful in maintaining all your records, i.e. vaccination, growth, medical history and medication history. Patients appreciate this service in case they lose their records or forget to bring them to the clinic. Such software can often help remind your patients regarding their visit to the clinic.

Mode of Payment

Besides cash, it is advisable to make arrangements for other mode of payment like credit cards and debit cards. Besides offering convenience to the patients it also reduces balance payments and bad debts.

PATIENT ATTRIBUTES

Cultural Background and Lifestyle Diversity

It takes much more than a prescription to have a cured and satisfied patient. It is very important to know about his religious beliefs, dietary habits, family setup (Nuclear or joint), daily routine, i.e., how much time parents can devote to house and the child.

It is important that all advice given should conform to the patients, religious and personal sentiments, e.g., egg as a source of protein would be acceptable to one section of the society, but however, becomes a taboo for the other

section, where one may have to look for other viable and locally available options, knowing the family setup greatly affects the quality of child care. In a nuclear family we have to be more sympathetic towards the mother and give her a patient hearing when she looks forward towards early weaning. Similarly knowing about the daily routines helps us anticipate problems. A working professional mother e.g., is more likely to fall into the trap of bottle feeding. Such a mother would need constant encouragement and moral support to keep the looming danger of bottle feeding away from the baby.

Managing an Angry Patient

Despite all our efforts to have a cured and satisfied patient, we are sometimes going to face a dissatisfied or angry patient. This anger could be emanating from a number of causes which have already been discussed. The patient is often aware of his anger but not fully aware of the cause. It is never a good idea to deal sternly with the patient or not to address his anger and go on with your job. The following techniques are useful for dealing with an angry patient.

Diffusion

Sometimes it is important to tell the patient that he or she appears to be upset. This at least opens the door for a dialogue. The following discussion could help us understand our shortcoming or the patient misgiving. This usually clears the bad air following which a fruitful consultation could start. This decreases the patient attrition rate and leads to a better bonding between the doctor and the patient.

Table 2: Certain do's and dont's of office practice

<i>Do's</i>	<i>Dont's</i>
<ul style="list-style-type: none"> • Accommodating appointment schedule • Attentive and smiling (Happy Glow Look) • Respect your patient • Formal dressing • Clean, aesthetic office space—conforming to functional needs • Give the patient his golden minutes • Trained and adequate manpower • Continuous enhancement of skills and knowledge • Communicate in patient-friendly language • Prominently displayed consultation and other charges • Address the dissatisfaction of the patient 	<ul style="list-style-type: none"> • Rigid non-accommodating attitude • Grumpy under confident look • Forgetting basic manners and etiquettes • Flashy and trendy attire • Cluttered and unorganized office • Hurried approach • “I will do it all” approach • Relying solely on experience • Excessive and confusing medical jargon • Oblivious of the economically weak • Routine consultation—oblivious of the discontent

Redirection

Many times the patient is upset with an issue not pertaining to you but since he or she is upset, the anger gets directed towards you. A simple approach of helping the patient in identifying the cause of their discomfort can ease the situation for the doctor. The patient who has identified the cause can handle it at a later time and a fruitful consultation can ensue.

Separations

There may be those rare instances where you are unable to address and disentangle the patient's anger despite all your efforts. If this happens, it is best to end the relationship. Approach the situation with a constructive approach and not a punishing attitude. Gently explain to the patient that it would be in patient's interest to look for a new doctor to sort out the problem. However, if you feel that this is happening a little too often, kindly look into your emotional health too.

Language Barrier

It is of prime importance that we should be able to converse with the patient in a language with which, both the doctor and the patient, are comfortable. Mostly this is a non-issue as most of us usually chosen to practice in geographical areas close to our home town and are conversant with the local language and dialect. However, using tools like Google translator or anyother similar software available on the net saves the day for everyone. In every situation be sure to speak softly and slowly so that the patient understands every word of what you say.

SUMMARY

In the end it is important to understand that our profession needs empathy and compassion our offices area is the area of our livelihoods but at the same time they are not a business center. We should never forget the economically weaker section and to adjust to their needs will always contribute towards our social responsibility.

At the end of the day we must sit back and go through our experiences and try to understand what we did right, which will need to be further strengthened and what created unpleasant situations, which will need changes in our approach. A suggestion box placed in the clinic will greatly help us in our effort to improve our office practice.

“Pursue excellence, gains will follow”

Facility Based Integrated Management of Neonatal and Childhood Illnesses

Rekha Harish, SS Slathia

Nearly half of the under five deaths (U5) occur during infancy and two thirds of infant deaths occur during neonatal period (41% of U5). The National Population Policy Goals aim at achieving an infant mortality rate (IMR) of 30/100,000 live births. The National Rural Health Mission (NRHM) launched in April 2005 reiterates this commitment. In order to achieve this goal, Government of India launched the integrated management of neonatal and childhood illnesses (IMNC) program which simplified and integrated the management of most common morbidities of children <5 years in a color coded stratification, helping the physician to first assess, then classify and finally treat the child. It also guided the physicians for the detection of danger signs which dictated the referral of sick children to the nearby health facility. Subsequently, it was realised that strengthening of available referral health facilities was also the need of the hour and it was essential to prepare standard guidelines keeping in view the available resources for managing these cases by both the medical officers as well as the staff nurses at the first referral units. This became one of the main objectives of RCH-II under NRHM.

Good quality prompt inpatient care for children is required at these facilities to increase the impact of appropriate interventions in reducing child mortality. According to the Bulletin on Rural Health Statistics 2007, the number of pediatricians in the country is only 898 as against the required number of 4045!!! Keeping in view the acute shortage of pediatricians at health facilities, it is imperative to build the skills of the health staff at these facilities to manage referred sick newborn and children. F-IMNCI is a facility based care for severely ill children, which is complementary to primary care for providing a continuum of care for severely ill children. Currently, it is the only comprehensive yet compact package which enhances the

skills of the health staff. It has been developed with inputs from various professional bodies such as Indian Academy of Pediatrics (IAP), National Neonatology Forum (NNF), WHO and UNICEF and field level experts. The introduction of F-IMNCI helps to build capacities of the health personnel at facility level to address newborn and childhood illnesses confidently, correctly and promptly to help in attaining the National goals despite acute shortage of specialists.

Facility based care chart booklet module explains the sequential process for managing sick young infants and children as soon as they arrive in the hospital. A brief review of this approach is covered in the following section:

FACILITY BASED INTEGRATED MANAGEMENT OF NEONATAL AND CHILDHOOD

Emergency Triage Assessment and Treatment

The guidelines for triage, emergency treatment and inpatient care of children including the newborns even at PHC level are illustrated vividly as shown in Flow chart 1. One learns how to carry out ETAT (emergency triage, assessment and treatment), which is the most important intervention in saving many critically ill children. The first step is triage—the process of rapid screening to decide to which of the following group(s) a sick child belongs to:

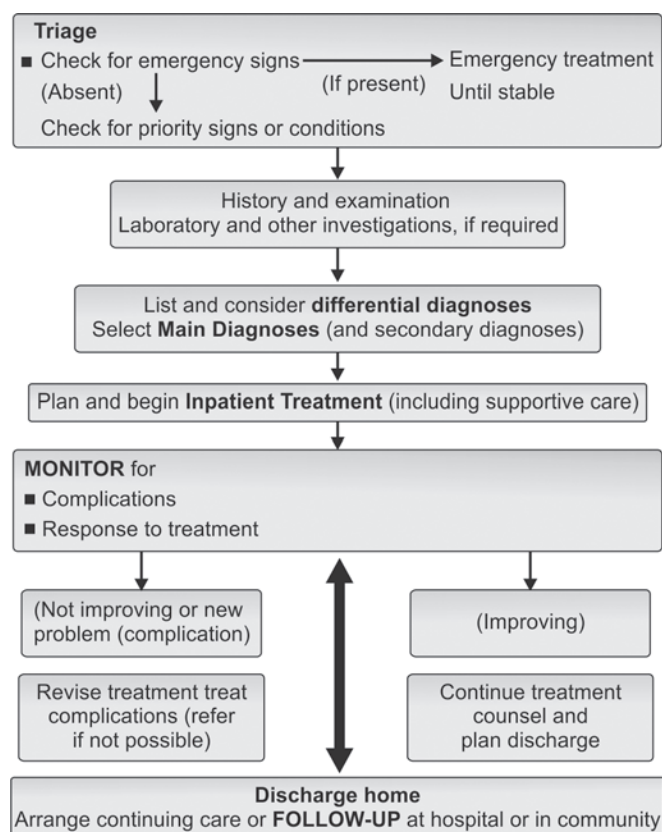

Those with emergency signs require immediate emergency treatment.

Those with priority signs need immediate assessment and treatment.

Children with no emergency or priority signs are treated as nonurgent cases.

After the child with emergency signs is stabilized, a detailed history is taken, examination and relevant laboratory investigations are performed.

Flow chart 1: Steps in the management of the sick child admitted to hospital: Summary key elements

TRIAGE OF ALL SICK CHILDREN

All sick children are assessed for airway, breathing, circulation, coma, convulsions and severe dehydration (ABCD) Flow chart 2. In view of the poor outcome in many small infants and severely malnourished children due to co-existent hypothermia and hypoglycemia, the management of these is detailed here before ABCD. Efforts are made to maintain euglycemia and euthermia while managing ABCD.

MAINTAINING TEMPERATURE

Maintaining temperature is an essential step in managing sick newborns and sick children, especially with shock or with severe acute malnutrition (SAM). As soon as a sick child is brought with temperature below 35.5°C or who is cold to touch (where thermometer is not available), maintain thermal environment as given below. Keep the infant dry and well wrapped. Cap, gloves and stockings are helpful to reduce heat loss. Keep the room warm (at least 25°C) making sure that there is no heat source directed straight at the newborn. Keep the baby under a radiant warmer and rewarm so as to bring the child's temperature to 36.5°C. Monitor temperature every half hourly for first 2 hours and then every 2 hourly.

TREATMENT OF HYPOGLYCEMIA

Check for blood glucose in all children presenting with emergency sign, those with severe acute malnutrition and all sick young infants:

If hypoglycemia is detected (defined as <45mg/dl for young infants and <54 mg/dl in older sick children beyond 2 months), give I/V bolus dose of 10 percent dextrose, in the dose of 2 ml/ kg for young infants, and 5 ml/ kg for older children. If blood glucose cannot be measured, give bolus dose as above.

Details of management of hypoglycemia in young infants are given subsequently.

MANAGEMENT OF AIRWAY AND BREATHING

The letters A and B in ABCD represent airway and breathing. If there is no problem with A and B look for C. The things to be looked are given in Flow chart 2.

If child is not breathing support breathing with bag and mask ventilation and continue as per basic life support (Flow chart 3): Basic life support for a young infant is different from that of an older child because of differences in anatomy and physiology.

MANAGEMENT OF AIRWAY IN A CHILD (>2 MONTHS) WITH GASPING OR WHO HAS JUST STOPPED BREATHING

Always ask and check for head or neck trauma before treating, as this will determine how much a child can be moved. If a child has trauma one must avoid further injury during assessment or treatment. It is also important to know the child's age because one will position an infant (under 12 months of age) differently from an older child.

HOW TO MANAGE THE AIRWAY NO NECK TRAUMA SUSPECTED (FIG. 1)

Child Conscious

- Inspect mouth and remove foreign body, if present.
- Clear secretions from throat.
- Let child assume position of maximal comfort.

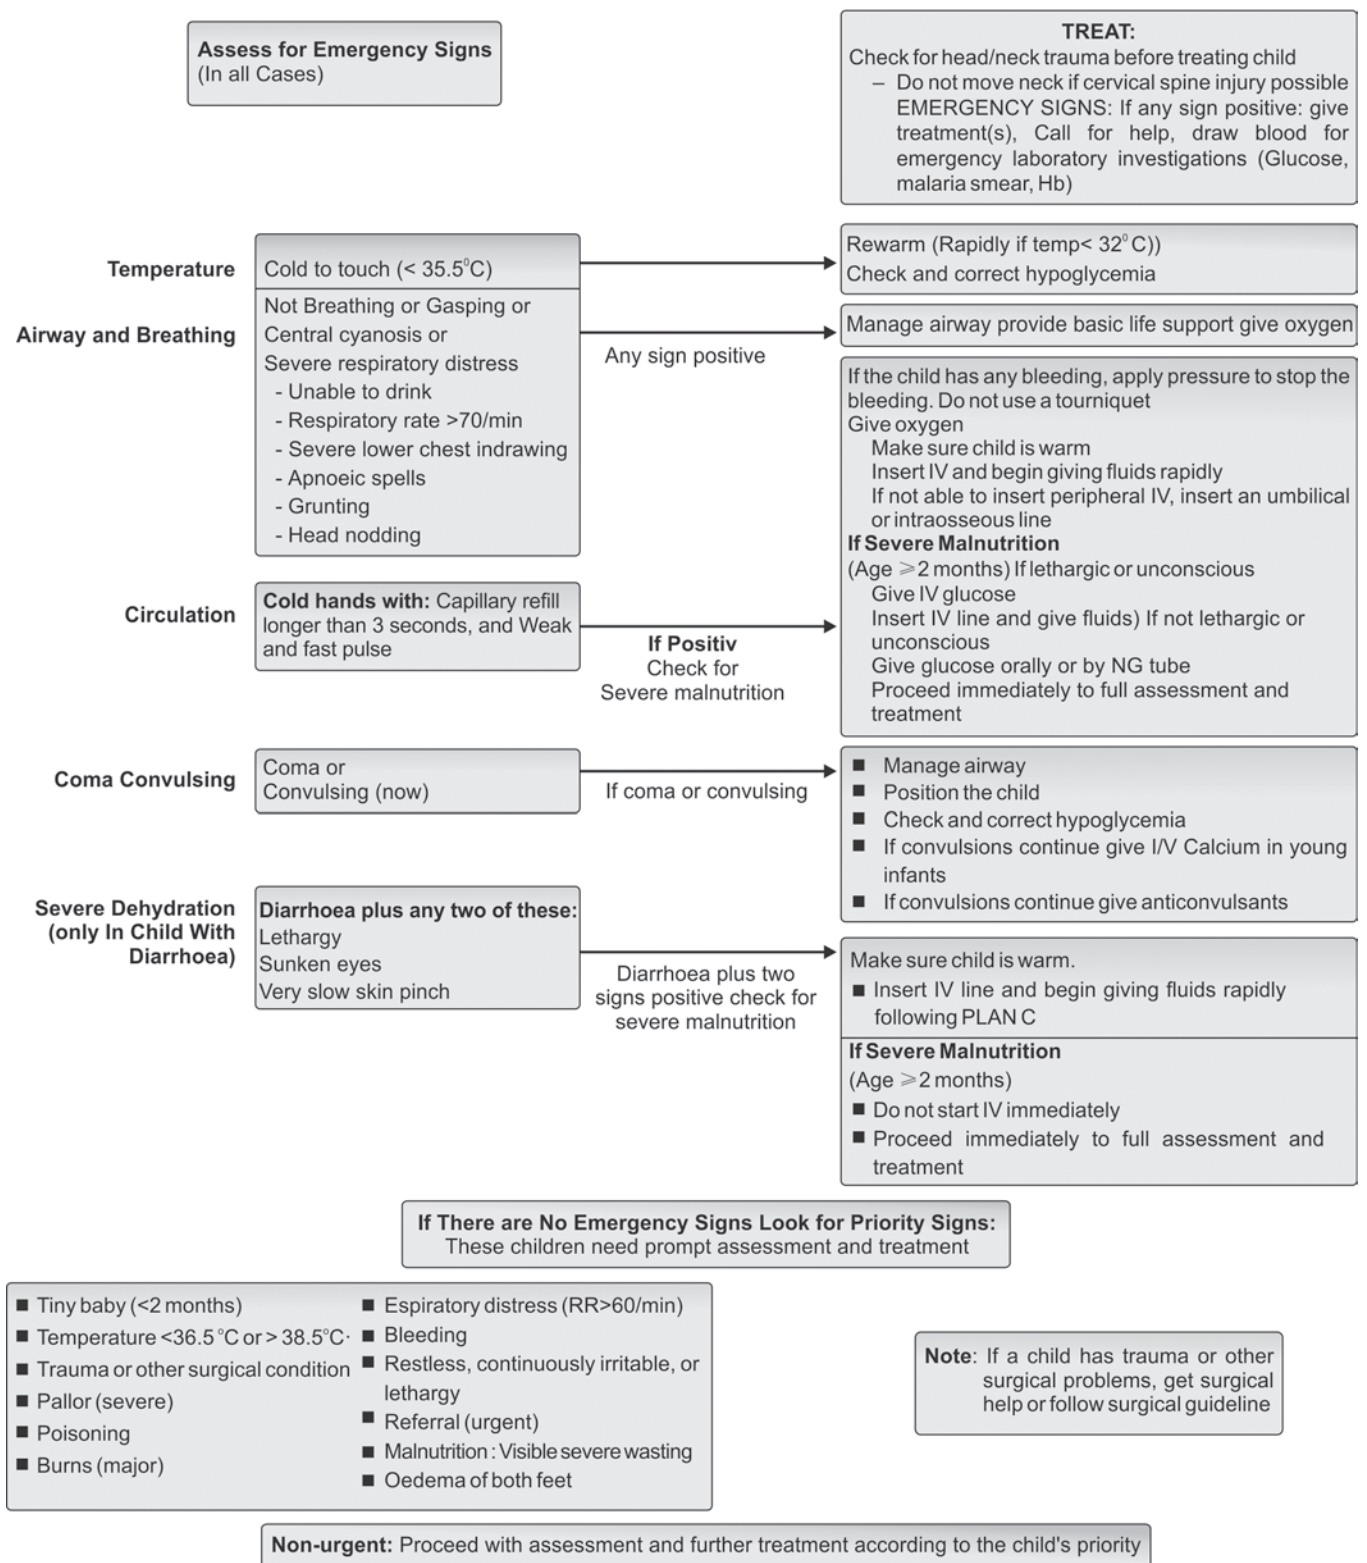

Child Unconscious

- Tilt the head as shown (Head tilt-chin lift maneuver).
- Inspect mouth and remove foreign body, if preclear secretions from throat.
- Check the airway by looking for chest movements, listening for breath sounds and feeling for breath.

Neck Trauma Suspected (Possible Cervical Spine Injury) (Fig. 2)

- Stabilize the neck. Inspect mouth and remove foreign body, if present.

Flow chart 2: Triage of all sick children

Flow chart 3: Providing basic life support

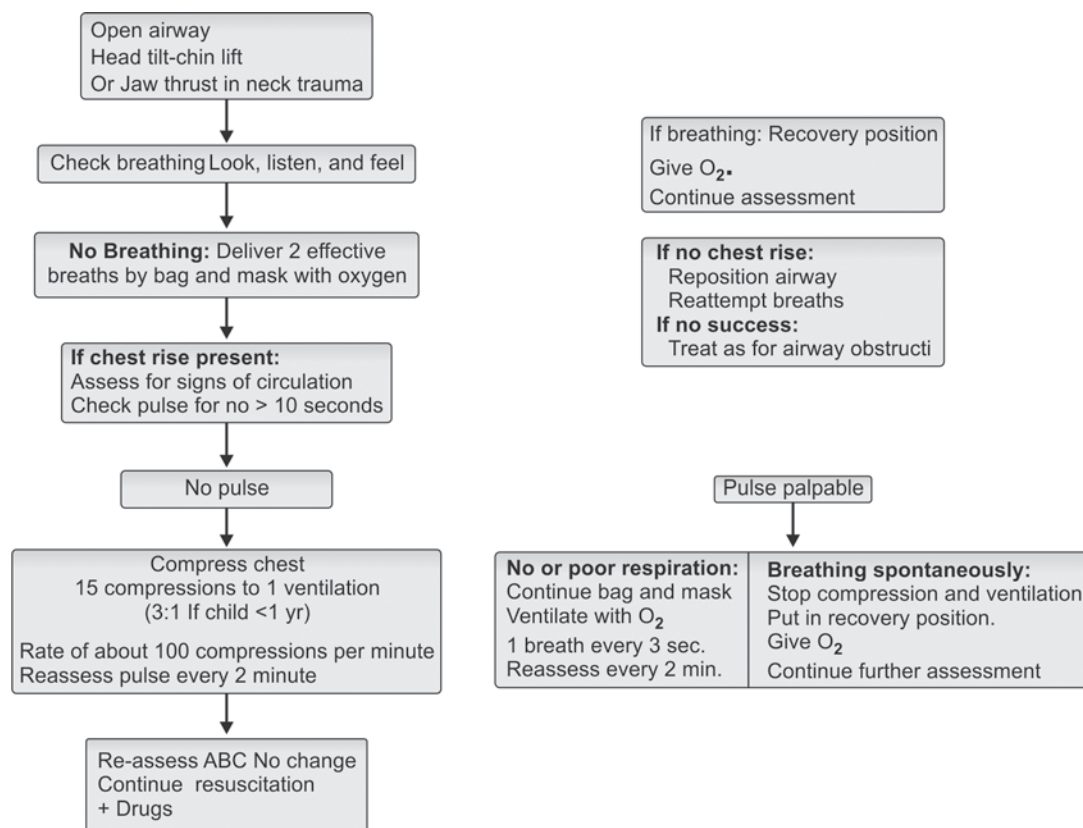

Fig. 1: No neck trauma suspected

- Clear secretions from throat.
- Check the airway by looking for chest movements, listening for breath sounds, and feeling for breath.

Use Jaw Thrust without Head Tilt

If after any of these maneuvers the child starts breathing, an oropharyngeal airway should be put and start oxygen.

Fig. 2: Neck trauma suspected

Ventilate with Bag and Mask

If the child is not breathing even after the above maneuvers or spontaneous ventilation is inadequate (as judged by insufficient chest movements and inadequate breath sounds), ventilate with a self-inflating bag and mask. The bag is used together with a face mask.

Call for help in any child who needs bag and mask since some of these children may additionally need chest compression. After two effective ventilations, check the pulse (femoral, brachial or carotid) for no more than ten seconds. If pulse is absent, the second person should start chest compression by thumb technique where the 2 thumbs are used to depress the sternum, while the hands encircle the torso and the fingers support the spine. Therefore, the 2 activities must be coordinated, with one ventilation interposed after every third

compression, for a total of 30 breaths and 90 compressions per minute.

Adrenaline 0.1 ml/kg (1:10,000) intravenous can be used in a child who does not respond to initial ventilation and chest compressions and his pulses are absent. Two such doses can be used 3 to 5 minutes apart.

Giving Oxygen to a Child with Respiratory Distress

A child with cyanosis or severe respiratory distress should be allowed to take a comfortable position of his choice and should be given oxygen. In these children begin oxygenation with a head box (8 – 10 L/min) or a face mask (5–6 L/min). When the child improves, catheter/prongs can be used for oxygen delivery. There are two possible sources of oxygen: Oxygen concentrators and Oxygen-filled cylinders.

Give oxygen at a high-flow rate (5–10 liters/min). If breathing difficulty is so severe that the baby has central cyanosis even with high-flow oxygen, organize transfer and urgently refer the baby to a tertiary hospital or specialized center capable of assisted ventilation, if possible.

Continue giving oxygen continuously until the child is able to maintain a SaO₂ >92 percent in room air. When the child is stable and improving, take the child off oxygen

for a few minutes. If the SaO₂ remains above 92 percent, discontinue oxygen, but check again 1/2 hour later, and 3 hourly thereafter on the first day off oxygen to ensure the child is stable. Where pulse oximetry is not available, the duration of oxygen therapy is guided by clinical signs, which are less reliable.

Oxygen can be given by: 1. Nasal catheter or 2. Nasal prongs or 3. Head box and face mask.

Circulation

The letter C in “ABCD” stands for Circulation, Coma and Convulsions. We assess the circulation for signs of shock after the airway has been opened by below given methods:

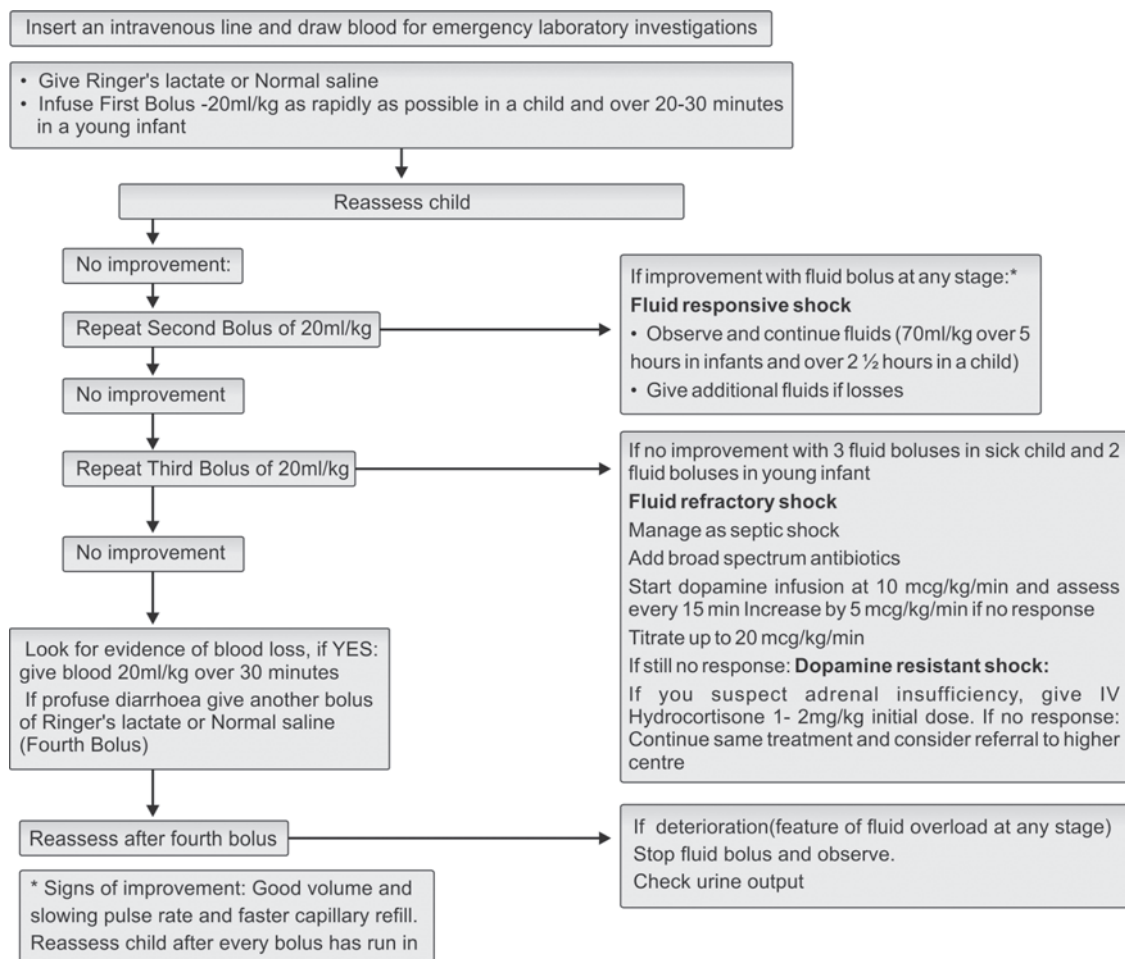

- Are the child's extremities warm?
- Is the capillary refill time longer than 3 Seconds?
- Is the pulse weak and fast?

SHOCK

Treatment of Shock: (Chart 4)

Treatment of shock requires teamwork. The following actions need to be started simultaneously:

Flow chart 4: Management of shock in a child without SAM

Note that blood pressure is not required for identifying shock because:

- Low blood pressure is a late sign in children and may not help identify treatable cases, and
- The correct size BP cuff necessary for children of different age groups may not be available.
 - Applying pressure to the nail bed for 3 seconds
 - Check the time to the return of the pink color after releasing the pressure.

Giving Fluids and Other Treatment for Shock

Young Infants

Fluid resuscitation: Infuse fluid bolus of 20 ml/kg of normal saline over 20 to 30 minutes. If no or partial improvement (i.e. tachycardia and CRT still prolonged), repeat a bolus of 20 ml/ kg of normal saline.

If the signs of poor perfusion persist despite 2 fluid boluses, start vasopressor support, except in infants with severe dehydration who should be treated as per Plan C of diarrhea management.

The most commonly used vasopressor in practice is dopamine. Usual starting dose is 5 to 10 µg/kg/min and if no improvement occurs, the dose can be increased by increments of 5 µg/kg/min every 20 to 30 minutes to a maximum of 20 µg/kg/min.

How to give Dopamine

- For giving 1 mcg/kg/minute of dopamine
- Amount of dopamine (mg) to be added = Weight in kg x6

- To convert this dose into amount to ml of dopamine divide by 40 (1 ml of dopamine = 40 mg of dopamine)
- Add this amount of dopamine (ml) to make 100 ml of total fluid
- 1ml/ hour of this fluid gives 1 mcg/ kg/ minute
- To give 10 mcg/ kg/ minute give 10ml/ hour or 10 microdrops/ minute (as 60 microdrops = 1ml)

Children Above 2 Months of Age

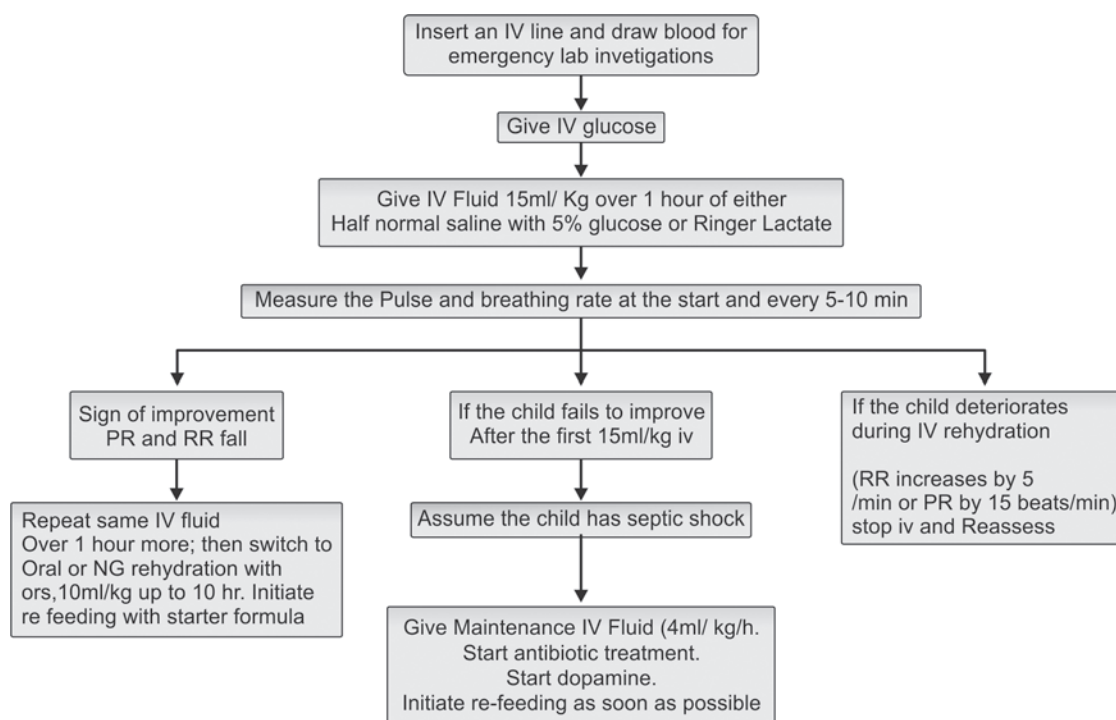

The recommended volumes of fluids to treat shock depending on the age/weight of child are shown in Chart 4.

If the child has severe malnutrition, you must use a different fluid and a different rate of administration and monitor the child very closely. Therefore a different regime is used for these children.

Management of Shock in a Child with Severe Acute Malnutrition (Chart 5)

If the child has severe malnutrition, you must use a different fluid and a different rate of administration and monitor the child very closely. Sometimes children with severe malnutrition have circulatory signs suggesting shock, but have sepsis rather than hypovolemia. It is important to follow the standard guidelines for caring for a child with severe malnutrition. If possible, avoid IV fluids—use a nasogastric (NG) tube or oral fluids. Only if the child is lethargic or unconscious and cannot swallow or tolerate an NG tube (e.g. vomiting), use ½-strength normal saline with 5 percent glucose or Ringer's Lactate at 15 ml/kg in 1 hour; but monitor carefully. Stay with the child and check

Flow chart 5: Management of shcoking a child with SAM

the pulse and breathing rate every 5 minutes. Discontinue the intravenous infusion if either of these increase (pulse by 15, respiratory rate by 5/min). If the child shows signs of improvement, give repeat IV 15 ml/kg over one hour and then switch to oral or nasogastric ORS. If the child fails to improve after the first 15 ml/kg IV, assume the child has septic shock.

Coma and Convulsions

C also represents “Coma and Convulsion”.

To help you assess the conscious level of a child is, a simple scale (AVPU) is used:

A Is the child Alert? If not,

V Is the child responding to Voice? If not,

P Is the child responding to Pain?

U The child who is unresponsive to voice (or being shaken) and to pain is unconscious.

A child who is not alert, but responds to voice, is lethargic. An unconscious child may or may not respond to pain. *A child with a coma scale of “P” or “U” will receive emergency treatment for coma as described below:*

Treatment of coma and convulsion

Treatment of coma and convulsions are similar and will be described together

Manage the Airway

Coma

Managing the airway is done in the same way as treating any child with an airway or breathing problem. This has been discussed earlier. Give oxygen for the emergency setting.

Convulsion

To manage the airway of a convulsing child gentle suction of oropharyngeal secretions should be done and child put in recovery position and oxygen started. Do not try to insert anything in the mouth to keep it open.

Put the Child in Recovery Position as Discussed Earlier

Insertion of an Oropharyngeal (Guedel) Airway

The oropharyngeal or Guedel airway can be used in an unconscious patient to improve airway opening.

How to Manage Convulsions?

Infant up to 2 Weeks of Age with Seizures

Secure IV access. If blood sugar <45 mg/dl, give 2 ml/kg 10 percent dextrose. If seizures continue: IV 10 percent Calcium gluconate 2 ml/kg over 10 minutes while monitoring heart rate (in young infants). If seizures continue: IV phenobarbitone 20 mg/kg over 20 minutes (Table 1). If no

control: Repeat phenobarbitone 10 mg/kg till a total of 40 mg/kg. If seizures continue: Give phenytoin 20 mg/kg over 20 minutes

Managing Convulsions Beyond 2 Weeks of Age

Diazepam is the first drug used to stop convulsions (anti-convulsant), if the child is convulsing. No drug should be given if the convulsion has stopped. Diazepam can be given by the rectal or intravenous route. Rectal diazepam acts within 2 to 4 minutes. In an emergency it is easier and quicker to give it rectally than intravenously, unless an intravenous line is already running. The dose is 0.5 mg/kg (0.1 ml/kg) rectally or 0.25 mg/kg (0.05 ml/kg)

Give 0.5 mg/kg diazepam injection solution per rectum by a syringe or a catheter. Hold the buttocks together for a few minutes. If you already have intravenous access, you can give the correct volume of drug directly, but slowly, in at least one full minute. Reassess the child after 10 minutes. If still convulsing, give a second dose of diazepam, rectally, (or diazepam intravenously slowly over 1 minute if an IV infusion is running). If convulsions do not stop after 10 minutes of second dose of diazepam, Injection Phenytoin can be given intravenously if access has been achieved. 15 to 20 mg/kg phenytoin is diluted in about 20 ml of saline and given slowly (not more than 1mg/ kg Phenytoin per minute). Alternatively phenobarbitone can be used in a dose of 15-20 mg/kg IV (in 20 ml 5% dextrose or saline) or IM. At this stage, seek help of a senior or more experienced person, if available. Diazepam can affect the child's breathing, so it is important to reassess the airway and breathing regularly.

DEHYDRATION

The letter *D* in the ABCD formula stands for Dehydration. Assessment and treatment of Severe dehydration (without severe acute malnutrition and with SAM) are given subsequently.

AGE First give 30 ml/ kg then give 70 ml/kg in ORS Solution per hour

If IV treatment not possible, give ORS 20ml/ kg/ hour for 6 hours (120 ml/kg) by NG tube.

Reassess an infant after 6 hours and a child after 3 hours. Classify dehydration. Then choose the appropriate plan (A, B, or C) to continue treatment as given in IMNCI.

Give oral antibiotic for cholera if child 2 years or older. If possible, observe the child for at least 6 hours after rehydration to be sure that the mother can maintain hydration by giving the child ORS solution by mouth.

Severe Dehydration with Severe Acute Malnutrition

This has been given in detail later in the section on SAM.

MANAGEMENT OF A SICK YOUNG INFANT

Give IV Fluids (Intravenous Fluids)

Type of fluid

- First 2 days: 10 percent dextrose in water.
- After 2 days: Use either commercially available pediatric maintenance fluid containing 25 mmol/L of sodium (e.g. Isolyte-P) otherwise prepare the fluid by adding 20 ml NS + 1 ml KCl + 79 ml of 10 percent dextrose to make 100 ml fluid. Monitor the IV infusion very carefully.
- Use a monitoring sheet.
- Calculate drip rate.
- Check drip rate and volume infused every hour.
- Check for edema/puffiness of eyes (could indicate volume overload).
- Weigh baby daily to detect excessive weight gain (excess fluid) or loss (insufficient fluid); adjust IV fluids appropriately.
- Adjust daily IV maintenance fluids appropriately if baby is receiving dopamine or any other infusions.

Introduce milk feeding by orogastric tube or breastfeeding as soon as it is safe to do so. Reduce the IV fluid rates as the volume of milk feeds increases in infants on orogastric feeds. Discontinue IV fluids once oral intake reaches 2/3rd total requirement. For babies who are able to breastfeed well, stop IV fluids.

HYPOGLYCEMIA

Check for blood glucose in all sick young infants.

- If hypoglycemia detected (defined as <45 mg/dl for young infants), give 2 ml/kg IV bolus dose of 10 percent dextrose.
- Start infusion of glucose at the daily maintenance volume according to the baby's age so as to provide 6 mg/kg/min of glucose in all cases of neonatal hypoglycemia.
- Recheck the blood glucose in 30 minutes. If it is still low, repeat the bolus of glucose (above) and increase infusion rate of glucose to 8 mg/kg/min. If blood sugar still remains low, then increase to 10 mg/kg/min. Once normal, monitor blood sugar every 4-6 hourly.
- Glucose infusion rates ≥ 10 mg/kg/min can result in glucose concentration >13 percent in the infused fluid. Under such circumstances infusion through peripheral veins is not recommended. It would require infusion through umbilical vein. If you cannot cannulate the umbilical vein refer the baby to a higher health facility.
- After the blood sugar has been stabilized step down the concentration of glucose by 2 mg/kg/min every 4 to 6 hourly ensuring that blood sugar remains normal. Allow the baby to begin breastfeeding. If the baby cannot be breastfed, give expressed breast milk using an alternative feeding method.

- As the baby's ability to feed improves, slowly decrease (over 6 – 12 hours) the volume of IV glucose if the baby remains euglycemic while increasing the volume of oral feeds. *Do not discontinue the glucose infusion abruptly to prevent rebound hypoglycemia.*
- If hypoglycemia is persisting at 10 mg/kg/min of glucose infusion, give one dose of Hydrocortisone: 5 mg/kg and refer to a higher health facility for further management of persistent hypoglycemia.

SEPTICEMIA

Common systemic bacterial infections in young infants include sepsis, pneumonia and meningitis and all these may present alike.

Signs of bacterial sepsis in a young infant are discussed in detail in IMNCI module.

More specific localizing signs of infection which indicate serious bacterial infection include:

- Painful joints, joint swelling, reduced movement, and irritability if these parts are handled.
- Many skin pustules/big boils (abscess).
- Umbilical redness extending to the periumbilical skin or umbilicus draining pus.

TREATMENT OF SEPTICEMIA

- Where blood cultures are available, obtain blood cultures before starting antibiotics.
- Provide supportive care and monitoring for the sick neonate.
- Start antibiotics; give injection ampicillin and gentamicin.
- Give cloxacillin (if available) instead of ampicillin if extensive skin pustules or abscesses as these might be signs of *Staphylococcus* infection.
- Most bacterial infections in neonates should be treated with antibiotics for at least 7 to 10 days except meningitis, arthritis, deep abscesses and staphylococcal infections which would require 2 to 3 weeks of therapy.
- If not improving in 2 to 3 days the antibiotic treatment may need to be changed, preferably as per microbial culture reports.

MENINGITIS

Suspect meningitis in an infant of septicemia if any one of the following signs are present:

- Drowsiness, lethargy or unconscious
- Persistent irritability
- High pitched cry
- Apneic episodes
- Convulsion
- Bulging fontanelle

To confirm the diagnosis of meningitis a lumbar puncture should be done immediately unless the young infant is convulsing actively or is hemodynamically unstable.

Treatment of Meningitis

Give Antibiotics

Give ampicillin and gentamicin or a combination of an aminoglycoside with third generation cephalosporin.

DIARRHEA

Diarrhea is uncommon in breastfed babies and is usually seen in babies who are not breastfed. The normally frequent or loose stools of a breastfed baby are not diarrhea. If the stools have changed from usual pattern and are many and watery, then it is to be labelled as diarrhea. Diarrhea may be a sign of systemic sepsis or UTI.

Assess for:

- Signs of dehydration
- Duration of diarrhea
- Blood in the stool

Approach to a Young Infant with Blood in Stool

Blood in stool in a young infant may be because of dysentery but is often due to surgical cause, necrotizing enterocolitis (NEC) or a bleeding diathesis.

Loose stools with blood:

- Active baby
- 1st week of age
- No signs of sepsis
- Manage as hemorrhagic disease of newborn. Give injection vitamin K 1 mg
- Signs of possible sepsis
- Manage as sepsis/NEC
- Abdominal mass
- Attacks of crying with pallor
- Urgent surgical referral.

Severe Persistent Diarrhea

If the young infant has diarrhea for 14 days or more, manage as case of severe persistent diarrhea.

Treat Severe Persistent Diarrhea

- Manage dehydration if present.
- Investigate and treat for sepsis: Start injection ampicillin and gentamicin.
- Encourage exclusive breastfeeding. Help mothers who are not breastfeeding to re-establish lactation. If only animal milk must be given, give a breast milk substitute that is low in lactose.
- Give supplemental vitamins and minerals for at least 2 weeks.

MANAGEMENT OF JAUNDICE

More than 50 percent of normal newborns and 80 percent of preterm infants have some jaundice. Jaundice can be physiological or pathological. If newborn is jaundiced, the

progression of skin staining is from head to toe and the level of bilirubin can be clinically assessed by extent of skin staining.

Check if

- Onset of jaundice is within 24 hours of life
 - *Clinical assessment:* Jaundice beyond abdomen
 - Baby is more than 14 days of age
- If anyone of the above is 'yes' then do the following investigations:
- Serum bilirubin (total/direct)
 - Hemoglobin/hematocrit
 - Blood groups of baby and mother
- (other investigations that may be required in some babies with suggestive history and relevant examination findings include sepsis screen, thyroid function test, LFTs, Ultrasonography of abdomen, etc.)

Treatment

Treatment of pathological jaundice is usually phototherapy or an exchange transfusion. (Refer for details to F-IMNCI participant manual)

NEONATAL TRANSPORT

Components of neonatal transport are: careful assessment of the baby, stabilization of the neonate, referral note, encouragement of mother to accompany baby, arrangement of a provider to accompany and warm transport.

Case Management of Children Presenting with Diarrhea

Diarrhea is common in children especially in those between 6 months and 2 years of age. 14 days of Acute diarrhea (14 days) causes dehydration and contributes to malnutrition.

Indications for hospitalization:

- Children with severe dehydration.
- Children with severe acute malnutrition.
- Children with associated comorbid conditions.

The assessment and classification of dehydration is described in Table 1.

Severe Dehydration (without Severe Acute Malnutrition)

Children with severe dehydration require rapid I/V rehydration with close monitoring, which is followed by oral rehydration once the child starts to improve sufficiently. In areas where cholera is endemic, give an antibiotic effective against cholera (Doxycycline is the first line recommended drug) to children above 2 years. The dose of doxycycline is 100 mg tab between 4 to 5 years and 50 mg (1/2 tab) between 2 to 4 years, single dose.

Management of severe dehydration with severe acute malnutrition is detailed later in section on SAM.

Table 1: Assessment and classification of dehydration

Classification	Signs or symptoms treatment
Severe dehydration Two or more of the following signs:	<ul style="list-style-type: none"> • Lethargy/unconsciousness • Sunken eyes • Unable to drink or drinks poorly • Skin pinch goes back very slowly • Give fluids for severe dehydration (Plan C)
Some dehydration Two or more of the following signs:	<ul style="list-style-type: none"> • Restlessness, irritability • Sunken eyes • Drinks eagerly, thirsty • Skin pinch goes back slowly • Give fluids for some dehydration (Plan B) • After rehydration, advise mother on home care
No dehydration Not enough signs to classify as some or severe dehydration	<ul style="list-style-type: none"> • Give fluids, zinc supplements and food and advise to continue ORS at home (Plan A)

Note: Ringer's lactate solution is the preferred I/V solution. If it is not available, normal saline can be used. Five percent dextrose solution is not effective and should not be used. In addition all patients should start to receive ORS solution at the rate of 5 ml/kg/hr when they can drink. This provides some base and potassium which may not be adequately supplied by I/V fluid.

Give 100 ml/kg Ringer's lactate solution (if not available, normal saline), divided as follows:

	30 ml/kg	70 ml/ kg
Infants (under 12 months)	1 hour*	5 hours
Children (12 months up to 5 years)	30 minutes*	2½ hours

* Repeat once if radial pulse is still very weak or not detectable.

- Reassess the child every 15 to 30 minutes. If hydration status is not improving, give the I/V drip more rapidly. Also give ORS (about 5 ml/kg/hr) as soon as the child can drink: usually after 3 to 4 hours (infants) or 1 to 2 hrs (children).
 - If I/V treatment not possible, give ORS 20 ml/kg/hr for 6 hrs (120 ml/kg) by NG tube.
- Assess an infant after 6 hours and a child after 3 hours. Classify dehydration again. Then choose the appropriate plan (A, B, or C) to continue treatment.
- Give oral antibiotic for cholera if child 2 years or older.
- If possible, observe the child for at least 6 hours after rehydration to be sure that the mother can maintain hydration by giving the child ORS solution by mouth.

DYSENTERY

Dysentery is diarrhea presenting with loose frequent stools containing visible blood. It is usually associated with fever, abdominal cramps and rectal pain. Most episodes in children are due to *Shigella* but can be caused by *Salmonella*, *E. coli*, *C. jejuni* and infrequently by *E. histolytica*.

Treatment of Dysentery

- In admitted children IM/IV Ceftriaxone (100 mg/ kg) once daily for 5 days may be used. For nonadmitted/discharged children give an oral antibiotic effective for *Shigella* (e.g. Ciprofloxacin, Cefixime).
- Prescribe a zinc supplement as done for children with watery diarrhea.

Provide Supportive Care

Supportive care includes the prevention or correction of dehydration (Assess the child for signs of dehydration and give fluids according to treatment Plan A, B or C.) and continued feeding. Never give drugs for symptomatic relief of abdominal pain and rectal pain, or to reduce the frequency of stools, as they can increase the severity of the illness.

MANAGE COMPLICATIONS

- Potassium depletion
- High fever
- Rectal prolapse
- Convulsions
- Hemolytic-uremic syndrome

Persistent Diarrhea

Persistent diarrhea (>14 days): Up to 20 percent of episodes of diarrhea become persistent. Persistent diarrhea often causes nutritional problems and contributes to deaths in children.

- Assess dehydration.
- *Screen for nonintestinal infections:* Pneumonia, UTI, Sepsis, Otitis media and Oral thrush.
- *Screen for intestinal infections:* Stool routine and culture if facility is available.
- In areas where HIV is highly prevalent, suspect HIV if there are other clinical signs or risk factors.

Treatment of Severe Persistent Diarrhea

Manage dehydration as Plan B or C and give antimicrobial therapy if:

- *Associated systemic infection:* Combination of parenteral Ampicillin and aminoglycosides is usually appropriate.
- *Associated severe malnutrition:* Use combination of Ampicillin and an aminoglycoside as for associated systemic

infection even if uncertain whether there is systemic infection.

- *Presence of gross blood in stools:* Give IM/IV Ceftriaxone (100 mg/kg) once daily or an oral antibiotic effective for *Shigella* (e.g. Ciprofloxacin) for 5 days.
- *Amoebiasis:* Give oral Metronidazole 10 mg/kg, 3 times a day for 5 days only if - Microscopic examination of fresh feces carried out in a reliable laboratory reveals trophozoites of *E. Histolytica* with red blood cells.
- *Giardiasis:* Give oral metronidazole 5 mg/kg, 3 times a day, for 5 days if trophozoites of *Giardia lamblia* are seen in the faeces.
- Give zinc supplements for 14 days (Tablet Zinc Sulphate 20 mg).

Zinc: Up to 6 months = 10 mg; >6 months = 20 mg

FEEDING

Children treated in hospital require special diets and the goal is to give a daily intake of at least 110 kcal/kg.

- Encourage exclusive breastfeeding. Help mothers who are not breastfeeding exclusively to do so.
- If child is not breastfeeding give a breast milk substitute that is low in lactose such as yoghurt or lactose free commercial formula. Use a spoon or cup; do not use a feeding bottle. Once the child improves, help the mother to re-establish lactation.

6 months or older feeding should be restarted as soon as the child can eat. Reduced lactose diet should be given 6 times a day to achieve a total intake of at least 110 calories/kg/day 6. Many sick children will eat poorly, until any serious infection has been treated for 24–48 hours. Such children may require nasogastric feeding initially.

Give supplementary multivitamins and minerals.

CASE MANAGEMENT OF CHILDREN PRESENTING WITH FEVER

Child Presenting with Fever

Three major categories of children presenting with fever are:

- Fever due to infection without localized signs (no rash).
- Fever due to infection with localized signs (no rash).
- Fever with rash.
 - Differential diagnosis of fever without localizing signs
 - Malaria, septicemia, typhoid, urinary tract infection
 - Fever due to infection with localized signs (no rash).
 - Meningitis, otitis media, mastoiditis, septic arthritis, pneumonia, viral upper respiratory tract infection.
 - Fever with rash.
 - Measles, viral infections, Meningococcal infection, dengue hemorrhagic fever.

SEVERE MALARIA

Presence of any of the following features in a child with microscopy or RDT positive for malaria indicates severe malaria:

- Altered consciousness
- Severe anemia (hematocrit <15% or hemoglobin <5g/dl)
- Hypoglycemia
- Respiratory distress
- Jaundice

Mortality may result in about 30 percent of such cases if timely treatment is not given.

Emergency Measures: to be taken within the First Hour

- Check and correct hypoglycemia. Treat convulsions. Manage shock, if present.
- If the child is unconscious, minimize the risk of aspiration pneumonia (insert a nasogastric tube and remove the gastric contents) treat severe anemia, if present. Antimalarial treatment provide supportive care if child is unconscious.

Also give treatment for bacterial meningitis if it cannot be excluded.

MONITOR THE CHILD

The child should be checked by nurses at least every 3 hours and by a doctor at least twice a day. Monitor temperature, pulse rate, respiratory rate and blood pressure every 6 hours, for at least the first 48 hours: Check blood sugar every 3 hourly until the child is conscious. Monitor the rate of I/V infusions. Fluid intake and output.

Meningitis (>2 Months Old)

Suspect meningitis if child has fever, vomiting, headache, irritability, inability to feed and seizures. Children with meningitis have neck stiffness with photophobia. Anterior fontanelle if open may be bulging. Early diagnosis is essential for effective treatment. The diagnosis is confirmed with a lumbar puncture and examination of the CSF. However, start the treatment immediately even if lumbar puncture is not possible or lumbar puncture cannot be done because the child has signs of raised intracranial pressure.

Treatment

Give antibiotics (for details refer to F-IMNCI participant Manual)

DENGUE FEVER

Dengue fever is suspected in an area of dengue risk if a child has fever lasting more than 2 days. Headache, pain behind the eyes, joint and muscle pains, abdominal pain, vomiting and/or a rash may occur but are not always present. It can be difficult to distinguish dengue from other common childhood infections.

Causative organism, dengue virus is an arthropode borne virus and has four serotypes (Den I, II, III and IV). *Aedes aegypti* a day time mosquito is the principal vector

in India, mostly seen in rainy season or in months following rainy season.

Diagnosis

Confirmation of diagnosis of dengue fever is based on demonstration of IgM antibody specific for dengue virus. Total leukocyte count is either normal or decreased. Platelet count is less than normal.

Treatment of Dengue Fever

Most children can be managed at home provided the parents have reasonable access to the hospital:

- Counsel the mother to bring the child back for daily follow-up but to return immediately if any of the following occur: severe abdominal pain; persistent vomiting; cold, clammy extremities; lethargy or restlessness; bleeding, e.g. black stools or coffee-ground vomit.
- Encourage oral fluid intake with clean water or ORS solution to replace losses from fever and vomiting.
- Give paracetamol for high fever if the child is uncomfortable. Do not give aspirin or ibuprofen as these drugs may aggravate bleeding.
- Follow-up the child daily until the temperature is normal. Check the hematocrit daily where possible. Check for signs of severe disease.
- Admit any child with signs of severe disease (mucosal or severe skin bleeding, shock, altered mental status, convulsions or jaundice) or with a rapid or marked rise in hematocrit.

SEVERE DENGUE

Severe dengue includes dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS).

Grading of Dengue Hemorrhagic Fever

DHF is classified into four grades of severity, where grades III and IV are considered to be DSS. The presence of thrombocytopenia with concurrent hemoconcentration differentiates grades I and II DHF from DF.

Grade I: Fever accompanied by nonspecific constitutional symptoms; the only hemorrhagic manifestation is a positive tourniquet test and/or easy bruising.

Grade II: Spontaneous bleeding in addition to the manifestations of Grade I patients, usually in the form of skin or other hemorrhages.

Grade III: Circulatory failure manifested by a rapid, weak pulse and narrowing of pulse pressure or hypotension, with the presence of cold, clammy skin and restlessness.

Grade IV: Profound shock with undetectable blood pressure or pulse.

Treatment of Severe Dengue as per Flow Chart 6 and 7

Most cases of DHF grade I can be managed on outpatient basis.

Indications for Hospitalization

Hospitalization for bolus intravenous fluid therapy may be necessary where significant dehydration has occurred and rapid volume expansion is needed because of reduced blood volume due to plasma leak. Signs in such cases include:

- Tachycardia
- Increased capillary refill time (>2 seconds)
- Cool, mottled or pale skin
- Diminished peripheral pulses
- Changes in mental status
- Oliguria
- Sudden rise in hematocrit or continuously elevated hematocrit despite administration of fluids
- Narrowing of pulse pressure (<20 mm Hg)
- Hypotension (a late finding representing uncorrected shock).

Manage Hemorrhagic Complications

- Mucosal bleeding may occur in any patient with dengue but is usually minor. It is due mainly to the low platelet count, and this usually improves rapidly during the second week of illness.
- If major bleeding occurs it is usually from the gastrointestinal tract, particularly in patients with very severe or prolonged shock. Internal bleeding may not become apparent for many hours until the first black stool is passed.

Consider this in children with shock who fail to improve clinically with fluid treatment, particularly if the hematocrit is stable or falling and the abdomen is distended and tender.

- In children with profound thrombocytopenia (<20,000 platelets/mm³), ensure strict bed rest and protection from trauma to reduce the risk of bleeding. Do not give IM injections.
- Transfusion is very rarely necessary. When indicated it should be given with extreme care because of the problem of fluid overload. If a major bleed is suspected, give 5 to 10 ml/kg fresh whole blood slowly over 2 to 4 hours and observe the clinical response. Consider repeating if there is a good clinical response and significant bleeding is confirmed.
- Platelet concentrates (if available) should only be given if there is severe bleeding. They are of no value for the treatment of thrombocytopenia without bleeding.

Provide Supportive Care

- Give paracetamol for high fever if the child is uncomfortable. Do not give aspirin or ibuprofen as this will aggravate the bleeding.

MONITORING

- In children with shock, monitor the vital signs hourly (particularly the pulse pressure, if possible) until the patient is stable, and check the hematocrit 3 to 4 times per day.
- Check the platelet count daily, where possible, in the acute phase.
- Keep a detailed record of all fluid intake and output.

Management of Typhoid Fever

Admitted patients are treated with ceftriaxone (80 mg/kg I/V or IM once daily). In ambulatory patients cefixime (20 mg/kg/day) can be used. In areas where sensitive strains have reemerged, use of chloramphenicol (25 mg/kg/dose, 8 hourly) is recommended. Duration of antibiotic treatment should be for 5 days after the child becomes afebrile or 10 to 14 days whichever is later. Other drugs used to treat typhoid fever include fluoroquinolones (ciprofloxacin 15 to 20 mg/kg/day in 2 divided doses, ofloxacin 10 to 20 mg/kg/day in 2 divided doses) and azithromycin (10 to 20 mg/kg/day).

The cases with typhoid fever should be closely monitored for complications like gastrointestinal hemorrhage, intestinal perforation, hypotension and shock. Antipyretics for fever and maintenance intravenous fluids may be required initially in cases who have poor oral intake.

MANAGEMENT OF CHILDREN WITH ANEMIA

Anemia is very common in children in developing countries. Severe anemia in a child is suggested by the presence of severe palmar pallor and may be associated with a fast pulse rate, difficulty in breathing, or confusion or restlessness. There may be signs of heart failure such as gallop rhythm, an enlarging liver and rarely pulmonary edema. Anemia/pallor should be looked for in each patient attending the health facility.

Nutritional anemia is the most common cause of anemia in children. Nutritional anemia results from deficiency of iron, folic acid and vitamin B₁₂. Iron deficiency anemia (IDA) commonly occurs in later part of infancy and preschool children particularly if they are not receiving adequate complementary feeding. Physical examination of children with IDA is usually unremarkable. They do not have significant hepatosplenomegaly or lymphadenopathy. Children having anemia due to folic acid and/or B₁₂ deficiency (megaloblastic anemia) may have hyperpigmentation of knuckles and occasionally bleeding manifestations due to thrombocytopenia.

Laboratory Diagnosis

Anemia in children less than 5 years is defined as Hemoglobin <11 gm/dl. Complete blood counts and examination of peripheral blood smear should be done in all anemic

children if possible. Blood films should be examined for malaria parasites particularly in high malaria risk areas. Stool examination for ova, cyst and occult blood. Blood counts should be performed using electronic cell counter if available. Children with IDA will have microcytic-hypochromic anemia. Usually leukocyte counts and platelet counts are normal. Children with folate and/or B₁₂ deficiency will have macrocytic anemia. These cases may have associated leucopenia and/or thrombocytopenia. Such cases should be referred for specialized investigation as in these cases other causes resulting in alterations in blood counts (bi/pancytopenia) and macrocytosis need to be excluded.

Treatment

IDA should be treated using oral iron 2 to 3mg/kg/day (dose of elemental iron). Older children who can take tablets can be given IFA tablets. Iron therapy should be continued 8 to 12 weeks after normal hemoglobin level is achieved. The children on iron therapy should be evaluated for response to treatment. Iron therapy results in prompt clinical response (return of appetite, decreased irritability). Check haemoglobin level after two weeks of therapy. Children not responding to treatment should be evaluated for compliance to treatment and adequacy of dose and presence of infections such as UTI and tuberculosis.

Blood transfusion is indicated in following situations:

- All children with Hb <4 gm/dl.
- Children with Hb 4 to 6 gm/dl with any of the following:
 - Dehydration
 - Shock
 - Impaired consciousness
 - Heart failure
 - Fast breathing
 - Very high parasitemia (>10% of RBC).

CASE MANAGEMENT OF CHILDREN WITH SEVERE ACUTE MALNUTRITION (SAM)

Malnutrition remains one of the most common causes of morbidity and mortality among children. The high case fatality rates among severely malnourished children can be reduced by using standardized and easily implementable protocols.

Criteria for Hospital Admission

- Weight for height/length <-3 z score of median of WHO child growth standards or
- Bipedal edema.

If weight-for-height or weight-for-length cannot be measured, use the clinical signs for visible severe wasting

Assessment of Severely Malnourished Child

A good history and physical examination is required for deciding the treatment but always start the emergency

treatment first. The details of history and examination can be recorded later.

Providing General Treatment for Malnutrition

The triage process and assessment of children with severe malnutrition and management of shock has already been discussed. Severe anemia, if present, will need urgent treatment.

There are 10 essential steps in two phases: an initial stabilization phase and a longer rehabilitation phase (Table 3). *Hypoglycemia and hypothermia are treated and prevented on urgent basis as these can kill the child.*

RECOGNIZE DEHYDRATION

Dehydration tends to be over diagnosed and its severity is overestimated in severely malnourished children. Many of the signs that are normally used to assess dehydration are unreliable in a child with severe malnutrition, making it difficult or impossible to detect dehydration reliably or determine its severity. Moreover, many signs of dehydration are also seen in septic shock.

Remember

A child with severe acute malnutrition may be dehydrated in the presence of oedema.

Treatment

Whenever possible, rehydrate a dehydrated child with severe malnutrition orally or through a nasogastric tube.

A severe acute malnourished child is at risk of hypokalemia due to reduced muscle mass. In addition to ORS start potassium supplements to prevent hypokalemia (syrup potassium chloride 15 ml of the syrup provides 20 meq of potassium).

Remember

Use IV rehydration only if the child has signs of shock and is lethargic or has lost consciousness.

Calculate Amount of ORS to Give

- Every 30 minutes for the first 2 hours 5ml/kg body weight
- Alternate hours for up to 10 hours 5- 10 ml/kg the amount offered in this range should be based on the child's willingness to drink and the amount of ongoing losses in the stool. Starter formula is given in alternate hours during this period until the child is rehydrated.
- If the child has already received IV fluids for shock and is switching to ORS, omit the first 2 hours treatment and start with the amount for the next period of up to 10 hours.

MONITOR THE CHILD WHO IS TAKING ORS

Signs of Overhydration

If you find signs of over hydration (increasing respiratory rate by 5/minutes and pulse rate by 15/minutes), stop ORS immediately and reassess after 1 hour.

Measures to prevent dehydration from continuing watery diarrhea are similar to those for well-nourished children.

- If the child is breastfed, continue breastfeeding.
- Give ORS between feeds to replace stool losses. As a guide, give 50 to 100 ml after each watery stool.

Shock in Severely Malnourished Children (See Flow chart 5)

Shock from dehydration and sepsis are likely to coexist in severely malnourished children. They are difficult to differentiate on clinical signs alone. Children with dehydration will respond to I/V fluids. Those with septic shock and no dehydration will not respond. The amount of fluid given is determined by the child's response. Overhydration must be avoided.

ELECTROLYTE IMBALANCE

- Give supplemental potassium at 3 to 4 meq/kg/day for at least 2 weeks. Potassium can be given as syrup potassium chloride; the most common preparation available has 20 meq/15 ml.
- On day 1, give 50 percent magnesium sulphate IM once (0.3 mL/kg up to a maximum of 2 ml), Thereafter, give extra magnesium (0.4–0.6 meq/kg daily) orally. If oral commercial preparation is not available you can give injection magnesium sulphate (50% which has 2 meq/ml) orally as magnesium supplements mixed with feeds for 2 weeks.
- Prepare food without adding salt to avoid sodium overload.

Table 3: The focus of initial management is to prevent death while stabilizing the child

	Stabilization Days 1-2	Days 3-7	Rehabilitation Weeks 2-6
• Hypoglycemia-----			
• Hypothermia-----			
• Dehydration-----			
• Electrolytes			
• Infection			
• Micronutrients No iron with iron---No iron with iron			
• Initiate feeding			
• Catch-up growth			
• Sensory stimulation			
• Prepare for follow-up			

INFECTION

Presume and Treat Infection

Assume all children with severe malnutrition admitted in a hospital have an infection and give broad spectrum Select antibiotics as shown in the Flow chart below.

All Admitted Cases

- Injection ampicillin 50 mg/kg/dose 6 hourly and injection gentamicin 7.5 mg/kg once a day for 7 days
- Add Injection cloxacillin 50 mg/kg/dose 6 hourly if staphylococcal infection is suspected
- Revise therapy based on sensitivity report.

For Septic Shock or Worsening/No Improvement in Initial Hours

- IV Cefotaxime 50 mg/kg/dose 6 hourly or injection ceftriaxone 50 mg/kg/dose
- 12 hourly plus injection amikacin 15 mg/kg/once a day

MENINGITIS

- IV Cefotaxime 50 mg/kg/dose 6 hourly or injection ceftriaxone 50 mg/kg/dose
- 12 hourly plus injection amikacin 15 mg/kg/once a day

DYSENTERY

- Injection ceftriaxone 100 mg/kg once a day for 5 days

Duration of Antibiotic Therapy Depends on the Diagnosis

- *Suspicion of clinical sepsis*: at least 7 days
- *Culture positive sepsis*: 10 to 14 days
- *Meningitis*: at least 14 to 21 days
- *Deep seated infections like arthritis and osteomyelitis*: at least 4 weeks.

Treat associated conditions: Malaria, HIV, tuberculosis, anemia, vit A deficiency, skin lesions, persistent diarrhoea etc.

MICRONUTRIENTS

Vitamin A, multivitamin supplement (should contain vitamin A, C, D, E and B₁₂ and not just vitamin B-complex), zinc, folic acid, copper and iron are added.

Initiate Feeding

- Give frequent and small nutrient rich feeds of low osmolarity and low lactose.
- Offer 130 ml/kg/day of liquids (100 ml/kg/day if child has severe edema), 80 to 100 Kcal/kg/day and 1 to 1.5 g/kg/day of proteins.
- Use nasogastric feeding till child takes orally 75 percent of all feeds.

- If child breastfed, continue breastfeeding but give the feed first.
- Ensure night feeds.

STARTER FORMULA

Starter formula is to be used during initial management. It is started as soon as possible and continued for 2 to 7 days until the child is stabilized. Severely malnourished children cannot tolerate usual amounts of proteins and sodium at this stage, or high amounts of fat. They may die if given too much protein or sodium. Starter formula is specially made to meet the child's needs without overwhelming the body's systems in the initial stage of treatment which provides 75 calories/ 100ml and 0.9 gm of protein/100 ml.

Feed the child starter formula orally, or by NG tube if necessary:

Oral Feeding

It is best to feed the child with a cup and spoon. Encourage the child to finish the feed. Encourage breastfeeding on demand between starter formula feeds.

Nasogastric Feeding

Use an NG tube if necessary, i.e. the child does not take 75 percent of the feed for 2 to 3 consecutive feeds.

Remove the NG tube when the child takes: 75 percent of the day's amount orally; or two consecutive feeds fully by mouth.

Record Intake and Output on a 24 Hours Food Intake Chart

Criteria for increasing volume/ decreasing frequency of feeds (Table 4):

- If there is vomiting, significant diarrhea, or poor appetite, continue 2-hrly feeds.
- If there is little or no vomiting, diarrhea is less than before, and most feeds are consumed, change to 3 hourly feeds.
- After a day on 3-hrly feeds: If there is no vomiting, occasional diarrhea, and most feeds are consumed, change to 4 hourly.
- The initial cereal based low lactose (low osmolarity) diet is recommended for those with persistent diarrhea (Table 5).

Table 4: Recommended schedule with gradual increase in feed volume

Days	Freq	Vol/Kg/feed	Vol/Kg/day
1–2	2 hourly	11 ml	130 ml
3–5	3 hourly	16 ml	130 ml
6 onwards	4 hourly	22 ml	130 ml

Table 5: Initial diets recommended in severe malnutrition: Starter formula

<i>Diets contents (per 100 ml)</i>	<i>Starter formula</i>	<i>Starter formula (Cereal based) Ex: 1</i>	<i>Starter formula (Cereal based) Ex: 2</i>
Fresh cow's milk or equivalent (ml)* (Approximate measure of one cup)	30 (1/3)	30 (1/3)	25 (1/4)
Sugar (g) (Approximate measure of 1 teaspoon)	9 (1 + 1/2)	6 (1)	3 (1/2)
Cereal flour: Powdered puffed rice (g) (Approximate measure of 1 level teaspoon)	— —	2.5 (3/4)	6 (2)
Vegetable oil (g) (Approx. measure of 1 level teaspoon)	2 (1/2)	2.5 (1/2+)	3 (3/4)
Water: make up to (ml)	100	100	100
Energy (kcal)	75	75	75
Protein (g)	0.9	1.1	1.2
Lactose (g)	1.2	1.2	1.0

*Can replace fresh milk 30 ml with 3.5 gm whole dried milk

MONITORING

- Amounts of feed offered and left over
- Stool frequency and consistency
- Vomiting
- Daily body weight.

CATCH-UP GROWTH

Recognize Readiness for Transition

Signs that a child has reached this phase are:

- Return of appetite (easily finishes 4 hourly feeds of starter formula)
- Most/all of the edema has gone.

Begin Giving Catch-up Formula Slowly and Gradually

Make a gradual transition from starter to catch-up formula.

Catch-up Formula

Catch-up formula is used to rebuild wasted tissues. It contains more calories and protein.

- Replace the starter formula with an equal amount of catch-up formula for 2 days. Give a milk-based formula, such as catch-up formula which contains 100 kcal/100ml and 2.9 g of protein per 100 ml.
- *Then on the 3rd day:* Increase each successive feed by 10 ml as long as child is finishing feeds. Continue increasing the amount until some feed remains uneaten. The point when some of the feed remains unconsumed is likely to occur when intakes reach about 200 ml/kg/day. After a gradual transition, give:

- Frequent feeds, unlimited amounts
- 150 to 220 kcal/kg/day
- 4 to 6 g of protein/kg/day.

If the child is breastfed, continue to breastfeed between feeds. However, breast milk does not have sufficient energy and protein to support rapid catch-up growth, so give catch up formula as indicated.

SENSORY STIMULATION

During rehabilitation provide:

- Tender loving care.
- A cheerful stimulating environment.
- Structured play therapy for 15 to 30 minutes a day.
- Physical activity as soon as child is well.
- Maternal involvement as much as possible (e.g. comforting, feeding, play).

Failure to Respond to Treatment (Table 6)

- Whether this occurred in all cases being treated (if so, a major review of case management is required).
- Whether this occurred in specific cases (reassess these children as if they were new admissions).

INADEQUATE FEEDING

Check

- That night feeds are given.
- That target energy and protein intakes are achieved. Is the actual intake (i.e. what was offered minus what was left over) correctly recorded? Is the quantity of feed

Table 6: Criteria for failure to respond to treatment

<i>Criteria after admission</i>	<i>Time</i>
Primary failure	
• Failure to regain appetite	Day 4
• Failure to start to lose oedema	Day 4
• Oedema still present	Day 10
• Failure to gain at least 5 gm/kg of body weight per day	Day 10
Secondary Failure	
Failure to gain at least 5 gm/ kg of body weight per day during rehabilitation for 3 successive days	
If the weight gain is <5g/ kg/ day, determine:	

recalculated as the child gains weight? Is the child vomiting or ruminating?

- Feeding technique: is the child fed frequent feeds, unlimited amounts?
- Quality of care: are staff motivated/gentle/loving/ patient?
- All aspects of feed preparation: scales, measurement of ingredients, mixing, taste, hygienic storage, adequate stirring.
- Whether complementary foods given to the child are energy dense.
- Vitamins and mineral supplements are given appropriately.

Look for Untreated Infection

If feeding is adequate and there is no malabsorption, suspect a hidden infection. The following are easily overlooked: urinary tract infections, otitis media, tuberculosis and giardiasis. In such a case:

- Re-examine carefully.
- Repeat urine microscopy for white blood cells.
- Examine the stool.
- If possible, take a chest X-ray.

PSYCHOLOGICAL PROBLEMS

Check for abnormal behavior such as stereotyped movements (rocking), rumination (i.e. self-stimulation through regurgitation), and attention seeking. Treat by giving the child special love and attention. For the child who ruminates, firmness, with affection, can assist. Encourage the mother to spend time playing with the child.

Monitoring Progress During Treatment

- If good weight gain, i.e. >10 g/kg/d, continue with the same treatment
- If moderate weight gain, i.e. 5 to 10 g/kg/day, check whether intake targets are being met or if infection has been overlooked
- If poor weight gain, i.e. <5g/kg/d, make a full assessment, particularly for:
 - Inadequate feeding

Table 7: Criteria for discharge from hospital care

<i>Criteria</i>	
Child	<ul style="list-style-type: none"> • Weight for height reached -1SD of median of WHO standards • Eating adequate amount of nutritious food that mother can prepare
	At home
	<ul style="list-style-type: none"> • Consistent weight gain • All vitamin and mineral deficiencies have been treated • All infections and other conditions have been treated or are being treated like anaemia, diarrhoea, malaria, tuberculosis • Full immunization programme started
Mother caretaker	or
	<ul style="list-style-type: none"> • Able to take care of the child • Able to prepare appropriate foods and feed the child • Has been trained to give structured play therapy and sensory stimulation • Knows how to give home treatment for common problems and recognizes danger signs warranting immediate medical assistance

- Untreated infection
- HIV infection
- Psychological problems
- Child is considered to have recovered when he reaches a weight for height 1 z score of median of WHO child growth standards.

Discharge and Prepare for Follow-up (Table 7)

Appropriate mixed diets are same as those recommended for a healthy child given at least 5 times a day providing 100 to 120 kcal/kg/day. Continue breast feeding. Every attempt should be made to manage the child till recovery and to avoid relapse and death after discharge. Follow-up regularly at 1, 2, 4 weeks, then monthly for 6 months and subsequently every 6 months for 2 years.

To conclude, with our own experience as a pediatrician we have not come across a presentation which is so exhaustive on pediatric management guidelines in such a compact form. It not only gives theoretical knowledge and reasoning but also imparts hands on training in a very friendly manner. Feedback reveals that the training is equally appreciated by all, including pediatricians, medical officers and paramedicals as despite being 'so much yet it is so easy to grasp'. The trained participants feel very confident in their ability to deal with neonates and children effectively. We take this opportunity to mention that time required to acquire skills, if extended to at least 30 days and made residential it would equip the participants with better practical skills particularly in learning procedures like IV lines without which they will not be confident and cannot render the services in desired manner. If implemented in letter and spirit we are very confident and hopeful that F-IMNCI strategy would definitely make a dent in NMR IMR and U5 mortality.

Recent Advances in the Management of Juvenile Idiopathic Arthritis

Sujata Sawhney

INTRODUCTION

Juvenile idiopathic arthritis (JIA) is the umbrella term that encompasses a heterogeneous group of chronic childhood arthritides of unknown cause. The clinical spectrum of disease in this group is variable: the child may have one or two swollen joints, or be ravaged by persistent fevers and aggressive polyarthritis. It is a chronic disease with an unpredictable course, marked by exacerbations and remissions.¹

The incidence of JIA ranges from 10 to 50 per 100000, which suggests that it is relatively uncommon in childhood, but the prevalence, is significant at 1:1000, suggesting that it is chronic in nature.²

The medical advances available across the globe are meaningless if their application is late. The single most important prognostic indicator is “early, appropriate treatment”. It is important to realize that diseases like JIA have two components: disease activity and disease related damage such as- contractures and deformities including joint erosions and leg length discrepancy. The latter have the potential to be permanent and disabling, but can be prevented in many patients with early appropriate treatment. Thus optimal therapy must be in the context of early referral to specialist centers.

It is now realized that the more rapidly inflammation can be controlled, the less likely it is that there will be permanent sequel. An adequate response is no longer acceptable. The possibility of absolute control of inflammation is a goal that should be pursued.

Increasingly, the aim of treatment is remission not improvement. Medically, though the major focus is on arthritis, other extra articular complications need consideration e.g. uveitis, serositis, growth retardation, and osteopenia.²

The issues discussed in this chapter are:

- General principles of management.
- Aims of management.

- Psychosocial issues in the care of these children
- Recent advances in the management of JIA
- Treatment for different subtypes of JIA
- Generic issues that arise in the care of children with JIA
- Current outcome studies and conclusion.

GENERAL PRINCIPLES OF MANAGEMENT

- Objective analysis of the disease activity in children with juvenile idiopathic arthritis is very important to guide therapy and assess improvement when the therapy is changed. In adult patients the disease activity score (DAS 28) score has been validated and is an excellent tool that can be conveniently used in an outpatient setting. Though no such numeric tool is available for children with juvenile arthritis, the American College of Rheumatology (ACR) pediatric 30 outcome measures are useful in clinical practice. Recently, definitions for inactive disease, clinical remission on medication and clinical remission off medication have been published for some subtypes of JIA and in fact the “Wallace criteria” as they are known are used to assess outcomes in newer trials and in daily clinical practice.⁴ A new multidimensional questionnaire for assessment of children with juvenile idiopathic arthritis (JIA) in standard clinical care has been recently developed. This is called the Juvenile Arthritis Multidimensional Assessment Report (JAMAR). It includes 15 parent or patient-centered measures or items that assess well-being, pain, functional status, health-related quality of life, morning stiffness, disease activity, disease status and course, joint disease, extra-articular symptoms, side effects of medications, therapeutic compliance, and satisfaction with illness outcome. In a study of 618 JIA patients the JAMAR was found to be feasible and to possess face and content validity.⁵

- Child centric team approach should be available for all children. A pediatric rheumatologist, a nurse specialist, physical and occupational therapist, a child psychologist and a social worker all work with the child's primary care pediatrician. Consultations with an orthopedic surgeon, dietician, and dentist should be available when required.
- Care is delivered by "shared care" which is extensively practiced in the western world: The tertiary pediatric rheumatology team guides specific therapy based on expertise and experience, while the local primary pediatrician offers routine care, growth monitoring, vaccination, drug monitoring and liaises closely both with the tertiary level team and community resources such as the school. This approach is well suited to deliver comprehensive care to the child with a chronic disease.
- Prognostication is not possible early on in the disease. Therefore, the initial approach must be vigorous in all children. This is very important, as it is now clear that radiologic joint damage occurs in most patients with systemic arthritis and polyarthritis within two years and in oligoarthritis within five years.⁶ There are some prognostic factors for different categories of JIA, but none that can give an accurate prognosis at the time of disease diagnosis.
 - *Systemic onset JIA*: A poor outcome in the systemic form correlates with markers of disease activity, such as fever and polyarticular involvement, within the first 6 months. Secondary amyloidosis is observed mainly in children with systemic JIA
 - *Oligo JIA*: The risk of joint destruction in this category is proportional to the severity of arthritis within the first 2 years. Chronic uveitis is a complication of JIA observed mainly in patients with oligoarthritis associated with positive antinuclear antibodies in serum.
 - Polyarthritis with a positive rheumatoid factor is associated with marked disability in adulthood.
 - *Psoriatic patients*: The risk of developing sacroiliitis is higher in male and HLA-B27-positive patients.
 - Enthesitis-related arthritis patients with lower limb, knee, and tarsal involvement also are at greater risk of developing sacroiliitis.⁷

THE AIMS OF TREATMENT OF JIA (TABLE 1)

These are conveniently divided into immediate and long term:

The immediate aims are

- To control inflammation
- Preserve vision (by screening and treating silent uveitis that is associated with ANA positive oligoarticular patients)

Table 1: Validated outcome measures for juvenile idiopathic arthritis trials

Active joint count (joints with swelling or with limitation of motion and tenderness/pain on motion)
Joints with limited range of motion
Parent/patient global assessment (measured on 0-10 visual analog scale)
Physician global assessment (measured on 0-10 visual analog scale)
Laboratory measure of inflammation (erythrocyte sedimentation rate, C-reactive protein)
Functional assessment (childhood health assessment questionnaire)
<i>A patient is considered to have responded if there has been an improvement in at least 3 variables by at least 30% and worsening in not more than one variable by more than 30%.</i>

- Relieve pain and discomfort
- Prevent deformities
- Preserve function

The longterm goals are to

- Minimize side effects of the disease and drugs
- Promote normal growth and development of the child
- Minimize impact of the chronic disease on the family
- Educate the child and family
- Finally rehabilitate the child.

PSYCHOSOCIAL AND EDUCATIONAL MANAGEMENT OF CHRONIC ARTHRITIS IN CHILDHOOD

This is as important as the medical care. Important issues while looking after this area are:

- The child should be strongly encouraged to attend school regularly.
- Children should determine their own level on activity.
- Participation in recreational activities and camps with other children with arthritis is very beneficial.
- Vocational evaluation is very important for the adolescent with arthritis.

RECENT ADVANCES IN THE MANAGEMENT OF JIA

Six important developments/advances have taken place in the last decade:

1. Appropriate use of NSAID's has been understood.
2. Intra-articular steroids have proved to be effective in treating joint disease.
3. Methotrexate is safe and effective.
4. Leflunamide is safe and effective as an alternative to methotrexate.
5. Biologic reaction modifiers (BRM's)—Etanercept and infliximab promise even further improvement in the risk benefit ratio.

6. High dose immunotherapy with transplantation is available in select centers.

Nonsteroidal Anti-inflammatory Drugs

The choice of NSAID's is empiric; clinical trials of NSAID's by the PRCSG (Pediatric Rheumatology Collaborative Study Group) in the USA concluded that 65 percent of the children who were going to respond would do so in the first 4 weeks. If a child does not respond it is logical to use an NSAID from a chemical class different to the one used earlier. Twenty five to thirty three percent of patients with oligoarthritis show a significant response to NSAID's alone. Aspirin is not used commonly any longer for the following reasons – the need for frequent dosing, greater frequency of liver enzyme abnormality, and the association of REYES syndrome.^{8,9}

Details of commonly used NSAID's are detailed in Table 2.

Cox 2 inhibitors have been shown to be effective in adults with significant reduction of gastrointestinal side effects. Rofecoxib has been recently withdrawn from the market due to cardiovascular adverse effects in adults. Though it was recently licensed for use in children, the use is now controversial.¹⁰ In the vast majority of children who tolerate non selective cox inhibitors well, there is no added advantage of using a cox 2 inhibitor.

Intra-articular Steroid Injections

Triamcinalone hexacetonide is the preferred steroid preparation due to the long-term and predominantly local effects, with a reported median duration of improvement for a period of 74 weeks. In 60 percent of patients the response persists for at least 6 months, in 45 percent there is no inflammation for at least one year. Accelerated linear growth of the involved leg is typical in this disease as the knee and ankle joints are the most commonly involved and the arthritis is frequently asymmetric. Early and continued use of IA steroid has been recently shown to be associated with less leg length discrepancy in young children with oligoarticular JIA.^{11,12} This agent is not available in India, where we use triamcinalone acetone.

Side effects of intra-articular steroids are very few. It is a very safe procedure that may need appropriate sedation in a child under 7 or 8 years of age. Problems after a joint injection are:

- Periarticular subcutaneous atrophy.
- Asymptomatic calcification.

There is no report of it being associated with any joint or cartilage damage^{13,14}

Methotrexate

Methotrexate is the sheet anchor for the treatment of polyarticular disease. There is evidence for the safety and efficacy of once weekly methotrexate in JIA. There are two methods of giving methotrexate either oral or injectable. The injectable route has many advantages over oral administration - it is well absorbed even at higher doses and is better tolerated. Nausea and gastrointestinal side effects are less when methotrexate is given parentally. Methotrexate is started at a dose of 15 mg/m²/week and built up as needed. Children require and tolerate larger doses than adults, sometimes at 1 mg/kg/week. Doses of 20 to 25 mg are therefore commonly used in children under six years. Thereafter children's requirement and tolerance both fall such that doses above 25 to 30 mg are unusual. An open randomized trial has recently shown that there is no advantage of giving methotrexate at doses of 30 mg/m².¹⁵ Most clinicians would switch to the subcutaneous route at doses greater than 0.5 mg/kg/week. Patients respond within three months, very occasionally is the response delayed beyond three months. The poorest response with methotrexate is in patients with systemic onset JIA (SOJIA). Folic acid at a dose of 1mg/day is often given to children receiving methotrexate and appears to lessen the toxicity and increase the tolerability of the drug. Precautions to be exercised while the patient is on methotrexate are as follows: no live vaccination, avoidance of alcohol, and no pregnancy while on the drug. Regular monitoring of hemoglobin, white cell count, platelets and liver function tests every 4-6 weeks is mandatory.^{16,17}

Leflunamide

It is a DMARD licensed for the treatment of adults with active rheumatoid arthritis (RA). It is converted to an active metabolite that inhibits *de novo* synthesis of pyrimidine and prevents activation of T lymphocytes that are involved in the pathogenesis of RA. Blinded trials in adult patients have well proven the efficacy of this drug. At the doses used, some clinical benefit of methotrexate over

Table 2: Nonsteroidal anti-inflammatory drugs

NSAID	Total daily dose	Maximum daily dose	No. of doses/day	Side effects
Naproxen	10-20 mg/kg/day	1000 mg	2	Cutaneous pseudoporphyria
Ibuprofen	40-60 mg/kg/day	3200 mg	3 or 4	Well tolerated
Diclofenac	2.5 mg/kg/day	125 mg	2	Gastritis
Indomethacin	1.5-3 mg/kg/day	200 mg	2	Headache
Piroxicam	0.25-0.4 mg/kg/day	20 mg	4	Gastritis

leflunomide was observed in the first year of treatment¹⁸ A recent trial that recruited 94 children has shown that leflunomide is safe in children with polyarticular disease and has an efficacy similar to methotrexate.¹⁹

BIOLOGIC REACTION MODIFIERS (BRM)

Introduction

There are many cellular and molecular mechanisms that participate in inflammation in patients with juvenile arthritis. Specific biologic agents have been developed that can target one or more steps involved in the immune response.²⁰

Strategies for Intervention are

- *Interference with cytokines:* The biologic effects of T-cell derived and monocyte derived cytokines are responsible for clinical features seen in JIA such as arthritis, enthesitis, and systemic features such as fever. Cytokines are thus important targets for therapeutic manipulation. Evidence supports the role of TNF alpha in both the initiation and perpetuation of the rheumatoid process. Agents that block TNF alpha are excellent tools to reduce disease activity, improve function and even retard or reverse structural damage. Three anti-TNF agents available are etanercept, infliximab, and adalimumab. The other cytokines that can be manipulated are IL-1 and IL-6. Data is available for these agents and will be discussed in detail.
- *Tolerance induction:* Trials of oral type II collagen have been tried in adults and children, as there is documented auto immunity to type II collagen in both adult and juvenile arthritis. Studies in humans have shown variable results, but with advances in other areas this has not been further studied. Another agent called IJP-394 has been studied to induce B-cell tolerance in patients with lupus. It is not currently widely used.
- *Inhibition of MHC/antigen/T-cell receptor (TCR) interaction:* This is also called the trimolecular complex. If the initiating antigen was known, an immunization program could be developed to prevent disease. Another possible route of attack is to block the MHC sides by antiMHC antibodies. This is currently under study.
- *Inhibition of cellular function and cell to cell interaction:* T-cells are critical in initiating the rheumatoid process in both children and adults. They may however not be critical for perpetuation of synovitis. Trials using anti CD7 monoclonal antibodies, the use of CAM-PATH, and Anti CD 4 monoclonal antibodies has been disappointing. There is no trial as yet that has studied blocking cell to cell interaction for example interaction between T-cells and antigen presenting cells. Another promising approach has been to block co-stimulatory interactions between T and B cells, for example by inhibiting the CD40-CD40 ligand pathway

with anti-CD40 ligand monoclonal antibody or the B7 pathway with CTLA-4Ig. Initial results in adult patients look promising.

- *Apoptosis:* Strategies to correct defective apoptosis include using monoclonal anti-Fas antibodies and are currently experimental.

ANTI-TNF AGENTS

- Etanercept
- Infliximab
- Adalimumab

Double blind, randomized controlled studies have shown all three agents to be an effective therapy in patients with juvenile idiopathic arthritis (JIA). Currently these drugs are given to patients who do not respond to an adequate trial with methotrexate. Studies are underway in children to determine whether administration of anti-TNF agents early on in the course of the disease may induce remission.²¹⁻²⁴ Long term data is now available for treatment with etanercept: 8 years follow up of 26 patients on this medication showed that the drug had a prolonged efficacy, the overall exposure-adjusted rates of serious adverse events (SAEs) remained stable (0.12 per patient-year), and the rate of medically important infections (MIIs) remained low at 0.03 per patient-year.²⁵

Generic Issues with Anti-TNF agents

- Safety issues are a concern because of the ubiquitous role of TNF. To date the only consistent adverse event seen with etanercept has been injection site reactions. There should be caution, however, with using etanercept in patients with a serious infection, or recurrent infections or patients with untreated or latent tuberculosis. As of yet there has not been seen an increase of malignancies. Rare neurological and hematological events have been noted. Etanercept has been a significant addition to the armamentarium of medications for the treatment of RA, juvenile and psoriatic arthritis.
- Active tuberculosis may develop soon after the initiation of treatment with infliximab. Thus before prescribing the drug, physicians should screen patients for latent tuberculosis infection or disease. The risk of tuberculosis is more with infliximab than etanercept because as opposed to etanercept, it binds not only to soluble TNF-alpha but also to membrane TNF-alpha. It is however mandatory to screen all patients for latent tuberculosis prior to using any biologic agent. This is with a PPD test and chest X-Ray/CT scan of chest in doubtful cases.^{26,27}
- Infliximab is mouse chimeric antibody, is known to give infusion reactions and must be given in a hospital setting with adequate monitoring facilities.

- Though in the western world their use is open ended, in India these agents are prohibitively expensive and are used to reduce disease burden and are very seldom continued for years on end. The rough cost of etanercept therapy for a 30 kg child is 4.16 lakh rupees for one year; for infliximab it is 3.24 lakh rupees per year + incidental hospital charges for nine admissions in the first year. Adalimumab is not yet available in India.
- *Cancers and TNF blockers*: Recent reports have generated some concern about the risk of cancers in patients on TNF inhibition. This issue has been discussed by Cron in a recent paper.²⁸ There is a specific risk of developing hepatosplenic T cell lymphomas in children with inflammatory bowel disease (IBD) treated with a combination of azathioprine or 6-mercaptopurine (6-MP), and a monoclonal antibody (mAb) directed against TNF (e.g. infliximab or adalimumab). These combinations should therefore not be used. The absolute risks of malignancies in JIA patients on biologics are difficult to ascertain as JIA patients who are naïve to biologic agents may be at an increased risk of malignancies *per se*.²⁹

The three anti TNF agents are summarized in Table 3.

OTHER BRM'S

Anakinra

This is interleukin-1 receptor antagonist (IL-1Ra). It is a naturally occurring acute phase anti-inflammatory protein part of the IL-1 super gene family. It is an important physiologic regulator of IL-1 induced inflammatory activity. Anakinra is a human recombinant form of IL-1 Ra that is produced by recombinant technology in *E.Coli*. It is given daily by subcutaneous injection. In pediatrics it

is used in a dose of 0.1 mg/kg/day and it has been shown to be effective in etanercept resistant SOJIA patients.³⁰ A recently published paper evaluated the use of this drug in TNF naïve patients with SOJIA. This study, called the ANAJIS trial has shown that anakinra treatment is effective in SJIA, at least in the short term. It was also associated with normalization of blood gene expression profiles in clinical responders and induced a *de novo* IFN signature.³¹ To date, this molecule is unavailable in India.

Anti IL-6 Receptor Antibody/Actemra

There is evidence that IL-6 is important in the clinical features of SOJIA. Anti IL-6 receptor antibody MRA is a genetically engineered humanized monoclonal antibody that is produced by grafting the complementarity-determining region of mouse anti-human IL-6 receptor to human IgG₁. MRA has been used in a study on SOJIA patients in Japan where the results were dramatic with 70 percent JIA core set response in 100 percent of patients receiving 8 mg/kg/week. This was a preliminary study with only 11 children. An international multicenter trial is currently underway.³² A recently concluded randomized controlled study by Japanese workers showed that actemra was highly effective in children with poly JIA.³³ The drug has been shown to be effective in SJIA patients as well in the recent EULAR 2011 congress where the data from the TENDER study (OP006) was presented. The drug has now received US FDA approval for children with systemic onset JIA.

Stem Cell Transplantation in JIA

Autologous hemopoietic stem-cell transplantation (AHSCT) has been described as a possible treatment for severe

Table 3: Anti-TNF agents for JIA

Name	<i>Etanercept</i>	<i>Infliximab</i>	<i>Adalimumab</i>
Chemical content	Fully humanized	Mouse chimeric	Fully humanized
Chemical structure	P-75 soluble TNF receptor protein fused to human Fc region of human IgG ₁	Chimeric IgG ₁ Anti-TNF alpha antibodies—mouse antibodies and constant region of human antibody.	Recombinant human IgG ₁ monoclonal antibody
Binds to	Soluble TNF alpha	Soluble TNF alpha and membrane bound TNF alpha	Soluble TNF alpha and membrane bound TNF alpha
Half life	4 days	Weeks	2 weeks
Route	Subcutaneous	Intravenous (IV)	Subcutaneous
Dose	0.4 mg/kg/dose/twice weekly or 0.8 mg/kg once weekly	3-6 mg/kg/dose	24 mg/m ²
Frequency	By weekly or weekly	As 0, 2, 6 weeks and then every eight weeks	Every 2 weeks
Methotrexate use	Optional	Recommended (to prevent anti infliximab antibodies)	Optional
Risk of tuberculosis	+	++	++

autoimmune disease refractory to conventional treatment. The first four children with severe forms of juvenile idiopathic arthritis to receive AH SCT were reported in 1999. Collaborative European trials with strict entry criteria and pre transplant conditioning are ongoing. Patient selection is critical prior to undertaking this modality of treatment where the mortality has now come down from 14 percent to 5 percent.^{20,34}

Specific Treatment Modalities for Each Subtypes of JIA

Oligoarticular JIA

Intra-articular (IA) injections and appropriate use of Non steroidal anti-inflammatory drugs (NSAID's) is the mainstay of treatment for this subtype of JIA. If the child with oligoarthritis has persistent joint inflammation in spite of an NSAID for 2-6 weeks the joint must be injected to prevent leg length discrepancy and the attendant long-term morbidity. In the persistent oligoarticular group this is all that is required. Disease modifying antirheumatic drugs (DMARD's) are generally not recommended for this group, although occasionally methotrexate may be useful for difficult to control uveitis or when damage to a critical joint threatens function (wrist/hip). If the disease extends, methotrexate should be considered for the treatment.

A recent editorial in the pediatric rheumatology online journal has suggested that oligoarticular JIA is not always benign. Persistent elevation of ESR, long standing anemia, or difficult to control arthritis and/or uveitis are all indications for aggressive treatment/DMARD use.³⁵

Polyarthritis

Standard Treatment

- NSAID either alone for the very mild disease or in combination with methotrexate is the initial treatment regimen.
- Early introduction of DMARD's—usually methotrexate
- Rapid disease control with intravenous methyl prednisolone boluses, or oral steroids.

Other Strategies

- Data also supports the use of sulphasalazine in the treatment of polyarticular JIA, though tolerability is poor in one-third of patients.^{36,37}
- A double blind control trial recently concluded that leflunomide is a safe alternative to methotrexate.¹⁹
- Currently TNF blockers are reserved for patients resistant to methotrexate alone.²²

Systemic Onset JIA

Drug management of systemic onset JIA aims to alleviate both the systemic features and the arthritis. Some mild cases clear up spontaneously. The fever may be treated with ibuprofen 40-50 mg/kg/day, or naprosyn at a dose

of 20 mg/kg/day. In the more severe case steroids may be needed at a dose of 1 to 2 mg/kg/day. IV methylprednisolone is also used to induce remission at a dose of 30 mg/kg/day (maximum 500 mg) for three consecutive days, and may be repeated after one week. Methotrexate remains the DMARD of choice for the children who have arthritis. For the more severe cases management is challenging, and may need DMARD combination and/or repeated pulsing with methylprednisolone. Recently thalidomide has been shown to be effective for both the systemic and articular components of the disease. The first report of its usefulness came in 2002 and was followed up by a multicenter trial in 2004. The dose of thalidomide is between 3 and 5mg/kg/day. The patients need to be monitored for sensory neuropathy.^{38,39} The biologic agents used in this subcategory are TNF blockers, anakinra and MRA (anti IL-6).^{21,24,30,32}

Untreated, systemic onset JIA can be complicated by macrophage activation syndrome (also known as hemophagocytic syndrome) which presents with persistent fevers, drop in the platelet count, lowering of the ESR, and liver function abnormalities with coagulopathy. This condition has a high mortality and is best treated with IV methylprednisolone and cyclosporin.^{40,41}

Enthesitis Related Arthritis

This group is believed to represent the adult equivalent of ankylosing spondylitis and reactive arthritis. The difference is that peripheral arthritis and not sacroiliitis is the main clinical feature. The treatment of choice for the peripheral arthritis in this group is sulphasalazine at 25-50 mg per kg per day, using doses as high as 2 gm/day. The NSAID of choice in this group is indomethacin. With significant systemic manifestations of the disease methotrexate is often added. Biologics have a role to play in management of all components of the disease: peripheral arthritis, enthesitis, uveitis and sacroiliitis.^{41,42}

Psoriatic Arthritis

Asymmetric involvement of small joints especially the DIP joints and dactylitis is characteristic of psoriatic arthritis. Significant nail pitting often precedes arthritis. The skin and joint disease may not always follow the same course. In addition to local skin treatment NSAIDs/IA steroids are used for localized disease involving a few joints, and methotrexate is used for aggressive disease involving multiple joints.^{41,42}

American College of Rheumatology 2011 Guidelines for Management of JIA⁴³

These recently published recommendations cover the initiation and safety monitoring of therapeutic agents in the treatment of JIA and include

- Nonsteroidal anti-inflammatory drugs

- Intra-articular glucocorticoid injections
- Non-biologic disease modifying anti-rheumatic drugs
- Biologic DMARDs.
- Systemic glucocorticoids for the treatment of the systemic features of systemic arthritis.

Of note, these recommendations divide JIA into 'treatment groups' instead of the JIA categories set forth by International League of Associations for Rheumatology.

The recommendations are focused on early use of TNF blockade and anakinra in children (which are prohibitively expensive), there is no role of steroids to induce remission and the categories of prognosis in each subtype are complex to follow. A treatment pathway for a subset of children with SOJIA and poor prognostic markers even suggests use of upfront anakinra. For these reasons the suggestions are not directly applicable in India.

Generic Issues in the Management of JIA

Uveitis

Standard treatment of uveitis is the use of topical methyl prednisolone and mydriatics to prevent synechiae. Methotrexate and other DMARDs have been tried, but there is no clear evidence that they are especially useful in uveitis resistant to steroid treatment. The benefit seen with methotrexate is evident at higher doses, when used subcutaneously or intravenously. Uveitis in JIA is silent and painless except in children with enthesitis related arthritis that have acute painful anterior uveitis. Thus, it is mandatory that patients with JIA be electively screened for uveitis at regular intervals, as untreated uveitis is known to cause visual loss and morbidity.^{12,40,44}

When should Methotrexate be Stopped?

Up until recently there has been paucity of published data to support evidence-based decisions in this area. Most authors had suggested that discontinuation of methotrexate when treatment induced remission had persisted for less than 1 year frequently resulted in return of arthritis within 6 months of drug discontinuation.^{17,45} NSAIDs and other medications are discontinued prior to attempting withdrawal of methotrexate. This thought has been recently questioned with the publication of an article that looked systematically at methotrexate withdrawal from 364 children with JIA when they entered remission. This trial randomized the children into two groups: one group continued the treatment for a further 6 months and the other for 12 months. Twelve month withdrawal of methotrexate compared with a 6-month withdrawal did not reduce the relapse rate in patients with JIA in remission. The second aspect of this study was to look at myeloid related protein (MRP) 8/14 concentrations in the serum of these patients. MRP is a protein that is secreted by activated phagocytes and increases with inflammation. It is postulated that an increased MRP suggest ongoing disease at the local level

which cannot be picked up clinically or by markers used such as ESR and CRP. A level of 690 nanograms/ml was detected to be a cut off, suggesting that an increased level of MRP 8/14 in clinically normal children who have normal acute phase responses are at a risk of flare when the methotrexate is discontinued.⁴⁶

Combination DMARD Therapy

Combination therapy is the rule rather than the exception in treating adult rheumatoid arthritis (RA), where use of weekly methotrexate along with daily hydroxychloroquine and sulphasalazine appears to give good results without any increase in toxicity.⁴⁷ This approach is reserved for the difficult to control JIA patient who does not respond adequately to subcutaneous methotrexate at a dose of up to 30 mg/ m². Failure to respond adequately or poor tolerability can occur in approximately a quarter of these children. In addition to the combination suggested above

- Etanercept/other BRMs and/or leflunamide may be used.
- Cyclosporin may be combined with methotrexate.
- Pulsed methylprednisolone may be used at regular intervals.
- Cyclophosphamide may be tried^{22,24,48}

There are no controlled studies of combination DMARD therapy in JIA.

Care of the Adolescence, Transition Issues, and Compliance

JIA is a chronic disease, with a third of patients carrying the disease into their adult years. Delayed adolescence both physically and emotionally is being recognized more widely and adolescent centered services to aid transition to adulthood have a major role to play in the long term care of the patient with JIA. Transition to adult care is a process that begins in the adolescent age. Attention to vocational skills, independent living skills, and self-advocacy warrant careful care and planning. Compliance with the treatment regime including medication, blood monitoring, exercises, splint usage and regular visits to health professionals are demanding on the child and family. Multidisciplinary teams under one roof are ideally suited to deliver this care. Patient and parent education and incorporation of the needs of the child and family members in planning care are essential to ensure that the patient adheres to the plan.^{49,50}

Physiotherapy and Occupational Therapy

The therapists are the key personnel to restore function and strength of affected joints and musculature. Together they plan a treatment program that incorporates a range of exercises, stretches for the joints, and activities of daily living. The occupational therapist has two important roles: to provide custom made splints to maintain joint position especially for the wrist and the knee joint,

and assist children whose disability requires modification of the environment. Children and adolescents both can improve aerobic endurance through participation in weight bearing physical conditioning programs without any disease exacerbation or increased pain. They can also achieve decreased joint signs and symptoms through increased physical activity. Lastly the therapist is usually the key person to educate the parents, and school personnel to ensure integration of therapy goals into the child's daily routine.⁵¹

Osteoporosis and Growth Retardation

There are many factors that adversely affect bone mass in children with JIA. Active arthritis has a well-known osteopenic effect around joints (periarticular osteopenia) and often systemically. Medications used in arthritis, especially steroids also have a known osteopenic effect. Decreased physical fitness and participation in organized sport, in addition to poor vitamin D and calcium intake contribute to the low bone mineral density (BMD). Interventional studies are lacking, and until sound evidence is available the following strategies are generally employed to optimize bone mass in children with JIA: aggressive control of disease activity, avoidance of corticosteroid use, and optimizing physical activity and calcium intake.

Bisphosphonates—alendronate has been recently shown to be effective in treating secondary osteoporosis in juvenile idiopathic arthritis. This drug crosses the placenta and is highly teratogenic. It is thus mandatory for patients to avoid pregnancy during the duration of treatment and for up to six months after discontinuation. Finally, growth hormone also improves the growth retardation and osteoporosis, particularly where the disease is stable but not in remission.

The best strategy to maximize growth is aggressive disease control, nutritional support and judicious yet minimal use of steroids.⁵²⁻⁵⁴

Can We Do Better?

One-third of children with JIA will have significant active disease well into their adult years and 50 to 60 percent have some form of disability or deformity in adulthood. Major disabilities occur in 10 percent of patients. This is data from the western world where a referral system is very well established, and where intervention is directed by multidisciplinary teams in tertiary level academic centers.^{1,50,55} Data from India suggests that after a median followup of 10 years up to 60 percent of patients have active disease. Certainly a major contributor here is delayed referral and delayed institution of disease modifying agents.⁵⁶

Development of new therapies has dramatically increased our ability to treat children with JIA, and hopefully induce remission in many children. There is though,

lack of evidence based treatment for some JIA subtypes. Effect of early aggressive therapy on the disease, early use of BRMs and potential of combination induction therapy needs to be studied. Multicenter control trials will provide this much needed evidence in the near future.⁵⁷

It is important for pediatric rheumatologists in turn to objectively assess patients, look at the core set criteria in these patients at set points in time,³ and guide therapy with the aim to achieve remission as per standard definitions recently validated for use for JIA patients.⁵³

Strategies likely to help children with JIA in our country are:

- Formal inclusion of pediatric rheumatology core curriculum both at the graduate and postgraduate levels in medical schools in India.
- Increased awareness amongst general pediatricians and orthopedic surgeons about the prevalence of JIA in India and the urgency of early referral of these patients to specialist centers.

Establishment of several tertiary level centers with good skill and expertise to direct care for these children.

Approach to a Child with Arthritis

Manjari Agarwal, Sujata Sawhney

INTRODUCTION

A child with complains of pain and/or swelling in joints is the most common cause of referral to a pediatric rheumatology clinic. These patients pose a diagnostic challenge due to an extremely broad differential diagnosis that needs to be considered.

The approach to a child with arthritis needs the following parameters to be carefully addressed:

- *The onset type:* Acute or chronic (the acute arthritis is one seen within 6 weeks of onset, whereas arthritis of more than 6 weeks duration is considered chronic)
- *The number of joints involved:* Single/more than one joint
- The type of joint involved
 - Small or large
 - Symmetrical or asymmetrical
 - Upper or lower segment
- Associated systemic features
 - Rash
 - Fever
 - Systems review
 - Uveitis
 - The lab markers
 - Family history.

This chapter will address the clinical approach to a child with joint pains.

CLINICAL PEARLS

The following clinical pearls should be kept in mind when these patients are evaluated:

Pain: It is not always present, many children with oligo JIA have a relatively asymptomatic swollen knee joint. Severe pain is seen in sepsis, trauma or bleed. Referred pain is also an important cause of a limp and needs to be differentiated from a swollen joint. Pain can be referred from the back (diskitis)¹ or from the hip to the thigh and

down the knee when the child can point towards the knee as the affected part.

Arthritis vs arthralgia

Arthralgia is a symptom or a complaint of pain in the joint made by the patient. It is not associated with a swelling or tenderness. Arthritis is a sign demonstrated on clinical examination and is defined as an intra-articular swelling or the presence of 2 or more of the following signs: limitation in range of motion, tenderness or pain on motion, and increased heat or erythema.²

JIA or Not?

By definition, juvenile idiopathic arthritis (JIA) is arthritis present for at least 6 weeks commencing in a child before the 16th birthday, with other known diagnoses excluded.³

Diagnosing juvenile idiopathic arthritis in a child poses special difficulties due to a number of reasons:

- Paucity of symptoms
- Requirement of a clinical skill set to examine a young uncooperative toddler who is not weight-bearing
- Lack of a diagnostic test
- It remains a diagnosis of exclusion and excluding a multitude of conditions is difficult.

The following approach towards the history, examination and investigations helps to recognize the pattern of the joint involvement in a child and is helpful in reaching the correct diagnosis.

History: A systematic and detailed history gives 85 percent clue to the diagnosis. Onset of arthritis can be acute or chronic. An acute presentation of arthritis within few minutes to hours is suggestive of an acute bleed inside a joint as in hemarthrosis, post-traumatic or in infections. It could occur occasionally in a child with reactive arthritis. A history of trauma is often given as this brings a previously quiet joint to the attention of the parents.

Trauma is considered significant if it causes non-weight-bearing immediately after the event. Pain/swelling occurring days after trauma is often of no consequence except if it causes mechanical derangements. A history of a preceding infection of the gastrointestinal tract or the upper respiratory tract would point towards a postdysenteric reactive arthritis or acute rheumatic fever.

Detailed history regarding the site, localization of pain is to be elicited. The number of joints involved is also important as it provides a clue to the type of arthritis (oligoarticular vs polyarticular).

History of associated systemic features like fever, rash, acutely swollen lymph nodes in the neck or axilla are a pointer towards systemic arthritis or can also point towards a malignancy.

History of pain in detail helps differentiate between mechanical, inflammatory and sinister pain (Table 1). Site of involvement can also give certain clues in regards to the diagnosis (Table 2).

The three clinical presentations of a child with arthritis are as follows:

- Acute monoarthritis
 - Sick child with or without fever
 - Well child with or without history of significant trauma
- Chronic monoarthritis
 - Sick child
 - Well child
- Polyarthritis
 - With fever
 - Without fever.

Approach to Acute Monoarticular Arthritis (Flow Chart 1)

An acutely painful joint is an emergency and needs to be diagnosed at the earliest not only to alleviate pain but also to prevent damage to the joint. Septic arthritis needs to be ruled out at the earliest.⁴⁻⁶

A detailed history and thorough clinical examination go a long way in narrowing down the diagnosis. Radiography along with laboratory support helps in the confirmation of the diagnosis.

Table 2: Site of involvement

Hip

An infant screams with nappy change.
The child may drag leg or rotate entire leg outwards.
Referred pain from hip to thigh or knee is common (usually anterior or sometimes medially).
Look for wasting of buttock and thigh
Check for Trendelenburg gait.

Knee

Knee will usually be held flexed when painful.
Look for wasting of thigh, calf.
If knee is held straight, consider psychosomatic problems.

Ankle

Look for wasting of calf. This often means ankle pathology.
A swollen ankle may be easier to detect from behind, especially in a smaller child.

Infected toe/ foot

Check for enlarged lymph gland in groin.

History

The age of the patient, the type of onset and the presence or absence of constitutional features help in narrowing down the wide differential in these children.

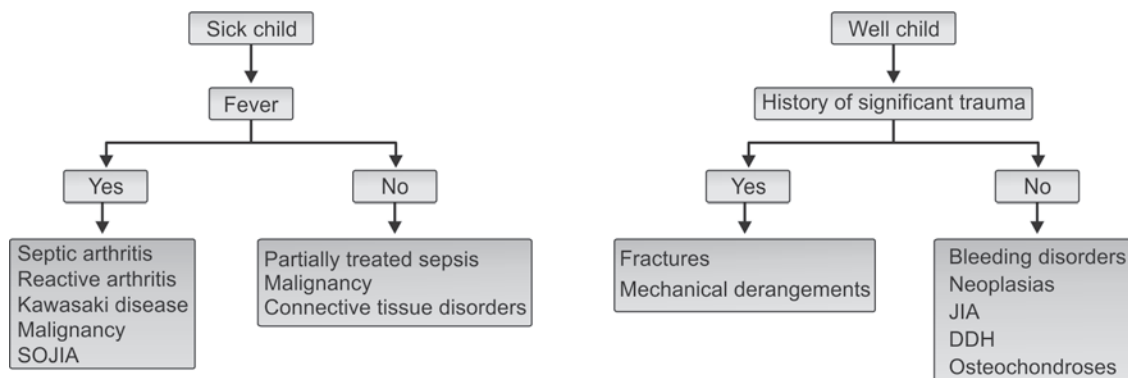

Age

- *Neonates*: A neonate presenting with an acutely swollen joint can have septic arthritis, NOMID (Neonatal onset multi inflammatory disease), developmental dysplasia of hip.
- *Infants*: Septic arthritis, Hemarthrosis due to bleeding disorders like hemophilia presents in infancy especially when the child is weight-bearing, developmental dysplasia of hip mild variant.
- *Childhood*: Septic arthritis, trauma, mechanical derangements, hypermobility, infiltrative disorders, reactive arthritis, juvenile idiopathic arthritis, skeletal dysplasia, etc. usually present in childhood.

Table 1: Types of joint pain

History	Inflammatory	Mechanical	Sinister
Onset	Insidious	Sudden/subacute	Insidious
Course	Fluctuant	Persistent	Persistent
Relation to time	More in morning	No relation	No relation
Relation to activity	Improves	Worsens	Worsens
Examples	Juvenile idiopathic arthritis	Slipped capital femoral epiphysis	Malignancy

Flow chart 1: Algorithm for acute monoarthritis

Onset

- *Sudden*: Sudden onset swelling and pain developing over minutes to hours is usually indicative of trauma causing fracture or soft tissue injury
- *Acute*: Pain and swelling of a joint over hours to days is suggestive of septic joint, reactive arthritis, hemarthrosis, acute rheumatic fever, etc.

Constitutional Features

Presence of fever, sore throat, weight loss, loss of appetite, diarrhea, dysentery, urethral discharge, history suggestive of uveitis, oral mucosal ulcers, hair fall, rash over skin, etc. is to be inquired into.

Nature of pain

- Is the pain severe enough to disturb the sleep of the child? (Osteomas)⁷
- Is there any early morning stiffness? (Inflammatory)
- Does the pain worsen after movement or does it get worse with exercise? (Inflammatory vs Mechanical)

Site and Distribution of Pain

In childhood arthritis recognition of the pattern of pain is very important as majority of the illnesses follow a pattern of joint involvement which aids in the diagnosis.

To interpret the pattern correctly it is necessary to know the following:

- Where did the pain start from?
- Which joints are involved?
- Upper limb joints/lower limb joints
- What is order of involvement?
- Whether arthritis is migratory or nonmigratory?
- Is the joint involvement symmetrical or asymmetrical?
- Is joint pain part of a systemic illness?

Associated Medical Illnesses

Psoriasis, inflammatory bowel disease, tuberculosis, etc.

Drug History

Long-term steroids can cause avascular necrosis, retinoids, anticonvulsants can unmask or exacerbate the articular manifestations of lupus.

Family History

History of arthritis, psoriasis.

Examination

General Examination

Complete head to toe examination is required.

Weight and height should be taken and growth charted if previous records available.

Look for alopecia, pallor, redness of eyes, cataract, icterus, rash, lymphadenopathy, nail pitting, thickening of skin, pigmentation, psoriasis, oral ulcers, nodules, Raynaud's phenomenon, etc.

Systemic Examination

CVS: Heart rate, murmurs

Abdominal examination: Visceromegaly

Respiratory System: Dyspnea, intercostal retractions

CNS: Headaches, neuropsychiatric manifestations (pointing towards SLE) need to be ruled out

Local Examination

Inspection: Warmth, Swelling, Redness

Look for soft tissue swelling

Examination: Movements of the joint

Ascertain whether the swelling is articular or periarticular

Enthesitis is to be ruled out by examination of the entheses especially the Tendo-Achilles.

Laboratory Markers

- Complete blood count, ESR, CRP, Blood culture, ANA, ASO titre, throat swab

- Ancillary investigations for specific diagnosis like Hb electrophoresis for sickle cell disease, factor VIII and factor IX estimation for hemophilia.
- *Synovial fluid examination: (Synovial fluid aspiration):* Most important investigation should be done by an experienced person with all aseptic precautions. On the basis of synovial fluid aspiration the diagnosis can be divided into three broad categories, first the fluid can be hemorrhagic and the diagnosis is either hemarthrosis or pigmented villous nodular synovitis. If the cell count in the synovial fluid is between 1500 cells/mm³ to <50,000 cells/mm³, it is suggestive of inflammatory/reactive arthritis. If the cell count is more than 50,000 cells/mm³ it is indicative of septic arthritis.⁸ Synovial fluid culture can help identify the specific organism and the sensitive antibiotic can be given.
- *Radiography:* X-ray of the joint affected, MRI, bone scan. CT scan or MRI are increasingly being used to identify the cause of an acute monoarthritis specially after history of trauma or where the pattern of joint involvement is suggestive of JIA, e.g. an eight-year-old male patient presenting with knee effusion and Tendo-Achilles swelling, where MRI becomes the investigation of choice to document tendinitis for the diagnosis of Enthesitis related arthritis. MRI is also helpful in the early diagnosis as it picks up bone edema early on in the disease course which is a sensitive marker for an inflammatory process.

Approach to Chronic Monoarthritis (Flow Chart 2)

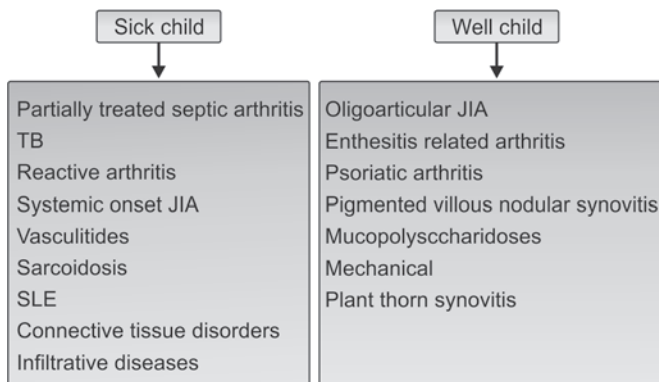

Arthritis for more than 6 weeks is termed as chronic.

History

Onset

Usually insidious, sometimes a partially treated acute septic joint can present as a chronic arthritis.

Flow chart 2: Algorithm for chronic monoarthritis

Pattern

In chronic monoarthritis recognition of the pattern of joint involvement is very important, e.g. in oligoarticular JIA, patient presents with few or absent constitutional symptoms and swelling or limitation of movement is often noted by parents. It is usually asymmetrical. A bilaterally symmetrical joint involvement is less common and is more in favor of a reactive arthritis.⁹

Constitutional Symptoms

Fever, rash, lymphadenopathy are present in systemic onset JIA, SLE and other connective tissue disorders. Arthritis in a child with juvenile dermatomyositis is associated with proximal myopathy and rash.

Nature of Pain

Migratory as in acute rheumatic fever¹⁰ relapsing as in hemarthrosis.¹¹

Duration

In chronic arthritis, duration of joint swelling is important as most diseases have a vertical presentation in children. The time period for classification of JIA and reactive arthritis is 6 weeks. If a child is suspected to be having oligoarticular JIA then a time period of 6 weeks should elapse before labelling the disease as other differentials like poststreptococcal reactive arthritis would usually subside by 6 to 8 weeks.

Past History

History of a joint swelling or of any illness like sore throat, diarrhea, dysentery recently (8 weeks), old trauma leading to mechanical derangement needs to be inquired about.

Examination

Similar as that of acute monoarthritis.

Investigations

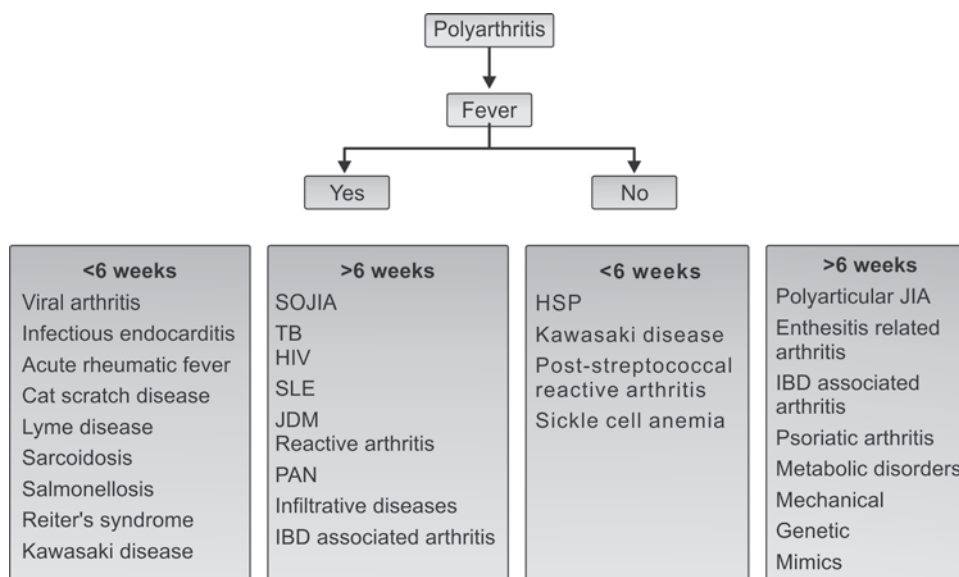

Laboratory Tests

Complete blood count, ESR, CRP, blood culture, quantiferon test, Mantoux test, screen for celiac disease if suspected, PT, aPTT, according to the clinical diagnosis.

Imaging

Forms the backbone of the diagnosis. Plain X-ray of the affected joint with the contralateral joint as control usually gives the clue to the diagnosis. MRI is superior to CT scan for the diagnosis as bone edema can be picked up earlier.

Flow chart 3: Algorithm for polyarthritis

Sometimes a bone scan is required to identify osteomyelitis, nonbacterial osteitis or bone infiltration.¹²⁻¹⁴

Approach to Polyarthritis (With and without fever) (Flow Chart 3)

Joint involvement lasting less than 6 weeks is termed as acute polyarthritis.

Joint involvement lasting beyond 6 weeks is chronic polyarthritis.

History

Onset

Polyarthritis can present with joint pains preceding constitutional symptoms or more commonly with fever and other constitutional symptoms presenting prior to onset of joint involvement.

Pattern

Recognition of joint involvement is imperative for the diagnosis, e.g. migratory or fleeting joint pain with fever preceded by sore throat is suggestive of acute rheumatic fever; additive pattern where some joints are involved at first and persist with recruitment of more joints later, e.g. polyarticular SLE.

Inflammatory vs noninflammatory: Pain in various joints due to hypermobility is noninflammatory as it appears at any time of day, (usually in the evenings after a day of hectic activity), is not associated with early morning stiffness and worsens with activity. Hypermobility should be considered in older child or adolescent with musculoskeletal pain principally confined to the lower limbs and back who lack objective evidence of joint swelling. A hypermobility

index called the Beighton score has been validated in Dutch children, although the cut off point differs for children depending on whether they are 10 years of age or older.¹⁵

On the contrary, inflammatory polyarthritis is worse in morning and improves with gentle activity.

Constitutional symptoms

History of irritable bowel, fever, redness of eyes, sore throat, rash, photosensitivity, early morning stiffness, oral ulcers, alopecia, etc. is to be inquired for by direct questioning.

Examination

Same as for monoarthritis.

Investigations

Infections need to be ruled out as per the clinical suspicion by ordering appropriate serology. ASO titre and throat swab can help in diagnosing acute streptococcal sore throat. Rheumatoid factor, Anti nuclear antibody, HLA B 27, etc. all help to confirm the diagnosis of various JIA subcategories.

Conclusion

In summary, a child who presents with arthritis needs a careful and detailed clinical evaluation. Acute conditions need to be identified at the earliest, specifically to diagnose septic arthritis that can destroy the joint in a few hours chronic polyarthritis needs to be identified and treated within a few weeks to prevent disease associated damage like joint contractures and leg length discrepancy. A systematic and

detailed history, careful clinical examination and few appropriate laboratory tests are all that is needed.

Approach to a Child with Connective Tissue Disease

Mehul P Jariwala, Sujata Sawhney

INTRODUCTION

Connective tissue diseases of children include a wide range of multisystem disorders, most of which may present as multiple and varying symptoms. The classic autoimmune CTDs include systemic lupus erythematosus (SLE), juvenile dermatomyositis/polymyositis (JDM/PM), systemic sclerosis (SSc), Sjögren's syndrome (SS), undifferentiated CTD (UTCD) and overlap syndromes, e.g. mixed CTD (MCTD).

Although some of these diseases have parallel conditions in adults (e.g. SLE and DM), they also differ from their adult counterparts in presentation, course, subtypes, responses to therapy, and morbidities. Additionally, it is well recognized that in childhood these conditions may “evolve”, with new features appearing over time, which may be more typical of a separate disease. For example, children with arthritis may develop lupus-like features. These areas of overlap between connective tissue disorders mean that each child needs to be carefully assessed and re-examined on a regular basis.¹

These disorders are characterized by abnormalities in the protein matrix within the connective tissue. They are defined as those syndromes which manifest as multiple organ system involvement. The pathogenesis of these diseases is heavily dependent on self-directed immune mechanisms. These diseases are grouped together as:

- They affect the body as a whole
- The disease usually has an immune activation
- They share a similar response to immunosuppression.
- Immune dysregulation leading to formation of antibodies and autoreactive T cells are the main basic abnormalities behind the causation of these diseases.

Children with connective tissue diseases are often difficult to diagnose as they present with multisystem involvement together with an array of diverse clinical signs and symptoms. The clinical presentation of connective tissue

disease in childhood can range from an acute severe illness mimicking a serious infection, to an insidious onset of disease that may only lead to recognition many months after the onset of symptoms.²

Collagen Vascular Disease or Connective Tissue Disease

Diseases in which inflammation or weakness of collagen tends to occur are referred to as collagen diseases. Collagen vascular disease is an umbrella term that covers a range of connective tissue disease. Collagen vascular disease is in fact a misnomer as this disease also affects vascular structures and molecules other than collagen. Collagen vascular disease in broad term can be divided primarily into two groups namely:

- *Heritable collagen vascular disorders:* Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, Stickler syndrome
- *Acquired autoimmune collagen vascular disorders:* SLE, JDM, scleroderma, Sjögren syndrome and MCTD.

This chapter deals with an approach to a child with a connective tissue disease and will look at salient features of the common CTDs in children and outline the clinical and diagnostic approach for these patients.

SYSTEMIC LUPUS ERYTHEMATOSUS

Epidemiology

Pediatric SLE (pSLE) is a prototypic autoimmune disease with a diverse array of clinical manifestations. Approximately 15 to 20 percent of SLE cases begin before age 19. The mean age at pSLE diagnosis is approximately 12 to 13 years. Data suggest an incidence of 6 to 18 cases/100000 white females, with higher rates among Blacks and Puerto Ricans.³⁻⁶

Clinical Features

The classic presentation of SLE is an adolescent female presenting with fever, arthralgia or arthritis who may have an erythematous butterfly rash extending over the cheeks and bridge of the nose. Mucocutaneous, musculoskeletal and kidney disease are the most common manifestations of pSLE.

Classification Criteria

The 1997 revised American College of Rheumatology (ACR) classification criteria are used by rheumatologists to classify SLE. The ACR system requires 4 of the 11 criteria to be present either at one time or over a period of observation to classify a patient to have SLE. The ACR criteria appear to be very useful in pediatric SLE as well, but of note are criteria for epidemiological purposes and not for diagnosis in the clinic (Table 1).⁷

Systems Involvement

SLE can involve many different systems in the body with their individual varied presentations:

- Hematological: Autoimmune haemolytic anemia, isolated thrombocytopenia, leucopenia, stroke in the young as a part of anti-phospholipid syndrome.
- Renal: Nephrotic syndrome, Acute nephritic syndrome and hypertension.
- Musculoskeletal: Arthralgia, Arthritis, myalgia, myositis, pain amplification syndrome.
- Central nervous system: Headaches, seizures, stroke, psychosis, chorea.
- Cardiovascular system: Pericarditis, Libmann Sacks endocarditis, myocarditis
- Mucocutaneous involvement: Photosensitivity, malar rash, “discoid-shaped, oral hard palatal ulcers,

alopecia, Raynaud phenomenon, panniculitis, livedo reticularis and vasculitic lesions.

- Gastro-intestinal involvement: Bowel vasculitis, lupus peritonitis, protein-losing enteropathy, celiac disease,⁹ Pancreatitis,¹⁰ splenomegaly, functional asplenia, hepatomegaly.
- Lung disease: Pleuritis, lupus pneumonitis, interstitial lung disease,¹¹ pulmonary hemorrhage, shrinking lung syndrome,¹² pulmonary vascular disease leading to pulmonary hypertension¹³
- Endocrine involvement: Hypothyroidism, corticosteroid induced diabetes mellitus, growth failure, ovarian failure and delayed puberty.
- Ocular disease: Retinal vasculitis manifestation by cotton wool exudates, central retinal vein occlusion, scleritis and episcleritis.¹⁴

Pediatricians should consider the diagnosis of pSLE in the following categories of patients:

- Prolonged marked constitutional symptoms without a diagnosis. The three common features that are present in most SLE patients and not covered in the SLE ACR criteria are fever, fatigue and weight loss. These are non-specific complaints and in India the child is often misdiagnosed to have tuberculosis
- Disease that involves more than a single organ system such as a photosensitive rash and arthritis; nephritis and pleuritis; haemolytic fever, photosensitive rash and weight loss
- Polyarthritis in an adolescent, especially a female,
- unusual presenting features (such as a myocardial infarction in a teenager), and
- Vasculitic rashes with constitutional features where the differential diagnosis would be a primary systemic vasculitis.

A thorough history and physical examination, a high index of suspicion and appropriate screening laboratory tests will allow the practitioner to make an early diagnosis.

The common differential diagnosis includes infections, malignancy, vasculitis and auto-inflammatory syndromes.

Laboratory Evaluation of pSLE

Screening

Is by the ANA (Anti-nuclear antibody) test. This is positive in over 95 percent of pSLE patients such that a negative ANA is usually a pointer *against* the diagnosis of SLE. These are specific antibodies produced against nuclear antigens. They can be detected by ELISA and Indirect immunofluorescence. The “gold standard” to measure ANA is by using Hep-2 cell line of human laryngeal epithelial carcinoma for indirect immunofluorescence. Both the titre and pattern of the nuclear antigen is studied.

Table 1: ACR criteria for classification of systemic lupus erythematosus⁸

- Malar rash
- Discoid rash
- Photosensitivity
- Mouth ulcers
- Arthritis
- Serositis (pleuritis or pericarditis)
- Renal disorder (proteinuria or urine sediment abnormalities)
- Neurological disorder (seizures or psychosis)
- Hematologic disorder (anemia, leukopenia or lymphopenia on two or more occasions, thrombocytopenia)
- Abnormal ANA titer
- Immunologic disorder (Positive finding of antiphospholipid based on: IgG or IgM anticardiolipin antibodies or Lupus anti-coagulant, abnormal anti-dsDNA or anti-Sm values)

ANA is positive in a low titre of 1:20 in many normal individuals. Malleson et al reported that 41 percent of ANA tests performed at British Columbia Children's Hospital in children without rheumatologic diseases were positive at titres of 1:20 or greater.¹⁵ A positive ANA in a dilution of 1:160 or more is suggestive of SLE or Mixed connective tissue disorder and the usefulness of the test is increased by reduction of false positive results.¹⁶

Further laboratory testing is guided by the following aims, which are true for evaluation of all CTDS where specific tests are carried out as per the diagnosis. For SLE patients:

- To study the extent of disease by doing the blood counts, LFTs, renal profile and urine analysis to look for an active sediment/ degree of proteinuria
- To study the severity of disease by looking at the C3/ C4/ DsDNA titres
- To exclude disease related mimics and exclude infections, e.g. with an X-ray Chest and Mantoux test.
- To look for thrombotic risk factors such as anticardiolipin antibodies, and lupus anticoagulant.

Outcome and Prognosis

The prognosis of children and adolescents with SLE who receive appropriate care is generally very good. Early recognition and treatment with immunosuppressants is usually associated with a profound improvement in the quality of life. Majority of patients experience a chronic course with periods of flare. The primary causes of an unsatisfactory outcome are poor compliance secondary to poor patient and family education, neurologic complications, intercurrent infections, renal disease, especially diffuse proliferative glomerulonephritis.¹⁷ Children with SLE are at increased risk for early atherosclerosis and coronary artery disease.¹⁸

JUVENILE DERMATOMYOSITIS

Epidemiology

Juvenile dermatomyositis (JDM) is the most common chronic idiopathic inflammatory myopathy of childhood. These children usually suffer from the characteristic skin and muscle abnormalities. The incidence of JDM is usually 0.19 cases per 100,000 per year for children younger than 16 years¹⁹ and average annual incidence rate is 3.2 cases per 1 million children.²⁰ It has a bimodal age distribution with one peak in the 5- to 14-year-old range, and a second peak in the 45- to 64-year-old range.²¹ The female-to-male ratio is 1.7:1 and the average age at onset is 7 years.²²

Clinical Features

JDM usually presents in four clinical phases:²³

- Prodromal period with nonspecific symptoms (weeks to months)

- Progressive muscle weakness and rash (days to weeks)
- Persistent weakness, rash, and active myositis (up to 2 years or longer)
- Recovery with or without residual muscle atrophy, contractures, and calcinosis.

Classic JDM manifests with an insidious progression of malaise, easy fatigue, muscle weakness, fever and a rash that may predate diagnosis by 3 to 6 months. The classical features of JDM presentation are with a heliotrope rash on the eyelids, proximal muscle weakness and Gottron's papules on the knuckles.

The muscle weakness in JDM is usually proximal with predominant involvement of the shoulder and the pelvic girdle muscles. Patients usually have difficulty in holding the head in the upright position or maintaining a sitting posture due to weakness of the anterior neck flexors. The skin overlying the involved muscle can become edematous and tender. Muscle examination usually reveals a marked proximal myopathy with positive Gower's sign and a Trendelenburg sign indicating the weakness of the hip abductors. Pharyngeal, hypopharyngeal, and palatal muscles are frequently affected increasing the threat of aspiration. Other less common musculoskeletal features include transient synovitis, arthralgia or arthritis.

Dermatomyositis sine myositis or amyopathic dermatomyositis is usually characterized by classic rash of JDM in the absence of clinical muscle involvement.

The specific mucocutaneous features of this disease are pathognomic of JDM. The three most typical cutaneous manifestations are heliotrope discoloration of the upper eyelids, Gottron papules, and periungual erythema and capillary loop abnormalities.²⁴ The heliotrope rash usually involves the upper eyelids and malar area with an indistinct margin. Gottron papules are the shiny, erythematous, scaly plaque like lesions seen on the extensor surface of the proximal interphalangeal joints of the hands predominantly. Photosensitivity occurs in up to 50 percent of patients.²⁵ With severe disease children with JDM can have vasculitic ulcers on extensor surfaces and gastrointestinal vasculitis as well.

Visceral vasculopathy occurs in a minority of children. Cardiopulmonary involvement in the form of nonspecific sinus tachycardia, pericarditis, hypertension, respiratory muscle weakness have also been reported.

Dystrophic calcification occurs in 12 to 43 percent of children and may occur in long-standing disease as large tumorous deposits in muscle groups, in bridging joints, or as an extensive subcutaneous exoskeleton. Lipodystrophy is another complication noted with JDM which may be generalized, partial or focal.²⁶ It is characterized by a slow but progressive loss of subcutaneous and visceral fat accompanied by hypertriglyceridemia, as well as by insulin resistance, abnormal glucose tolerance, acanthosis nigricans, hypertension and nonalcoholic steatohepatitis.²⁷

Diagnostic Criteria

Clinical Suspicion (Table 2)

JDM should be suspected in any child presenting with typical heliotrope rash, Gottron's papules with a proximal muscle weakness.

Laboratory Findings

Muscle enzymes

JDM is usually characterised by the presence of elevated muscle enzymes in the blood namely CPK, LDH, AST, Aldolase and ALT. It is important to remember that either of the mentioned muscle enzymes may be elevated in JDM. The flares of the disease are usually predicted by a combination of AST and LDH.²⁹ However, isolated LDH could be a marker of an underlying malignancy.

Autoantibodies

Antinuclear antibodies (ANAs) have been reported in a variable frequency of 10 to 85 percent.³⁰ Myositis-specific autoantibodies (MSAs) like those directed to the aminoacyl transfer RNA (tRNA) synthetases, signal recognition particle (SRP), and Mi-2 are seen exclusively in myositis patients with immunoprecipitation methods.³¹ Newer antibodies now identified in JDM include anti-p155 and anti-MJ.

Table 2: Bohan and Peter criteria for the diagnosis of JDM²⁸

Criteria for a diagnosis of juvenile dermatomyositis

- Symmetrical weakness of the proximal musculature
- Heliotrope discoloration of the eyelids, which may be accompanied by periorbital edema and erythematous papules over the extensor surfaces of joints, including the dorsal aspects of the metacarpophalangeal and proximal interphalangeal joints, elbows, knees, or ankles (i.e. Gottron papules)
- Elevation of the serum level of one or more of the following skeletal muscle enzymes: creatine kinase, aspartate aminotransferase, lactate dehydrogenase, and aldolase
- Electromyographic demonstration of the characteristics of myopathy and denervation, including the triad of polyphasic, short, small motor-unit potentials; fibrillations, positive sharp waves, increased insertional irritability; and bizarre, high-frequency repetitive discharges
- Muscle biopsy documenting histological evidence of necrosis; fiber size variation, particularly perifascicular atrophy; degeneration and regeneration; and a mononuclear inflammatory infiltrate, most often in a perivascular distribution
 - *Probable JDM:* Two criteria plus the typical rash for Dermatomyositis
 - *Definite JDM:* At least three criteria plus the typical rash for dermatomyositis

Nail Fold capillaroscopy

Nail Fold capillaroscopy can help analyze microvascular abnormalities like architectural disorganization, giant capillaries, hemorrhages, loss of capillaries, angiogenesis and avascular areas in dermatomyositis. It can also be used to monitor the effectiveness of the therapy.

Electrophysiology studies

Electromyography occasionally is useful in confirming the diagnosis of JDM. The characteristic electromyographic changes seen are myopathic motor units, decreased amplitude, denervation potentials (positive sharp waves), spontaneous fibrillations and high-frequency repetitive discharges.

MRI

Fat suppressed MRI and STIR image sequences have been used to diagnose JDM paving away the need of muscle biopsy. It demonstrates muscle edema and inflammatory changes by a hyperintense signal.³² MRI may be helpful in selecting a site for muscle biopsy.³³

Muscle biopsy

As mentioned previously with the advent of MRI, muscle biopsy is rarely required for establishing the diagnosis. Muscle biopsy demonstrates areas of muscle degeneration and regeneration with characteristic perifascicular atrophy with mononuclear cell infiltration.

Outcome and Prognosis

The long-term outcome of JDM has become increasingly important as the survival rate has improved. In general, the course of JDM is variable:

- Monocyclic disease occurs in about one-third of patients with findings of rash and muscle weakness. These patients have a good response to standard therapy
- Chronic continuous or polycyclic disease occurs in the remaining two-thirds of patients and is predictive of a poorer outcome.³⁴ These patients are at increased risk for persistent pain, calcinosis, and disability.

Risk factors for a poor prognosis include unremitting severe disease activity, cutaneous ulcerations, extensive calcinosis, dysphagia or dysphonia, advanced nail fold capillary abnormalities, a high serum creatine kinase level, a noninflammatory vasculopathy on muscle biopsy, and the presence of certain MSAs (such as antisynthetase and antisignal recognition particle autoantibodies). Delays in treatment and inadequate treatment are also important risk factors.

SCLERODERMA

Juvenile scleroderma syndromes are multisystem autoimmune rheumatic diseases characterised by is the presence of hard skin due to increased collagen deposition with onset before 16 years of age.

Scleroderma can be separated into two main categories:

Localized scleroderma (morphea) in which there is skin sclerosis but no vascular or internal organ involvement

Systemic sclerosis in which there is diffuse skin sclerosis involving many sites of the body together with internal organ involvement. This is further subdivided into diffuse cutaneous systemic sclerosis (dSSc) and limited cutaneous systemic sclerosis (lSSc).

JUVENILE SYSTEMIC SCLEROSIS

It is defined as symmetrical fibrous thickening and hardening (sclerosis) of the skin often combined with fibrous and degenerative changes in synovium, digital arteries, and certain internal organs, most notably the esophagus, intestinal tract, heart, lungs, and kidneys.³⁵

Epidemiology

Juvenile systemic sclerosis is extremely rare in children. Children younger than 10 years account for less than 2 percent of all cases.^{36,37} It occurs with equal frequency in boys and girls younger than 8 years old.

Clinical Features

The onset is often characterized by the development of Raynaud's phenomenon which is seen in almost 90 percent of the children. Cutaneous changes begin with edema, followed by induration of the subcutaneous tissues of the digits, hands, arms, and face and later sclerosis. Initial thickening of the skin is followed by later atrophy and areas of hypopigmentation or hyperpigmentation.³⁸ Morning stiffness, arthralgia, myositis are few of the musculoskeletal complaints. Dysphagia with gastroesophageal reflux, heartburn with postural aggravation, nocturnal aspiration and malabsorptive diarrhoea are sometimes noted. Cardiopulmonary involvement usually occurs in the form of arrhythmias, impaired ventricular function, cardiomyopathy, interstitial pulmonary fibrosis and pulmonary hypertension. Renal involvement is rarely seen in children but the abrupt onset of accelerated hypertension with acute renal failure (scleroderma renal crisis) is the most feared complication. The disease is further subdivided into two categories:

- Diffuse systemic scleroderma with skin involvement proximal to the elbows, presence of the anti-topoisomerase antibody and early involvement of the internal organs.
- Limited scleroderma has on the other hand skin involvement distal to the elbows, absence of Scl -70 and late internal organ involvement.

Classification Criteria (Table 3)

Laboratory Examination

Anemia of chronic disease, leukocytosis and eosinophilia occurs in approximately 15 percent of patients.⁴⁰

Table 3: Preliminary classification criteria for juvenile systemic sclerosis³⁹

Major criterion

- Sclerosis/ induration of the skin proximal to the metacarpophalangeal or metatarsophalangeal joints

Minor criteria

Skin

- Sclerodactyly
- Vasculopathy
- Raynaud phenomenon
- Nailfold capillary abnormalities
- Digital tip ulcers

Gastrointestinal

- Dysphagia
- Gastroesophageal reflux

Renal

- Renal crisis
- New-onset arterial hypertension

Cardiac

- Arrhythmias
- Heart failure

Respiratory

- Pulmonary fibrosis (HRCT/X-ray)
- DLCO
- Pulmonary hypertension

Musculoskeletal

- Tendon friction rubs
- Arthritis
- Myositis

Neurological

- Neuropathy
- Carpal tunnel syndrome

Serology

- Antinuclear antibodies
- SSc selective autoantibodies (anticentromere, antitopoisomerase I, antifibrillarin, anti-PM-Scl, antifibrillin or anti-RNA polymerase I or III)

A patient, aged less than 16 years, shall be classified as having juvenile systemic sclerosis if 1 major and at least 2 of the 20 minor criteria are present

High-titers of ANAs are frequently identified. Anti-topoisomerase I (anti-Scl-70) autoantibodies occur in at least 40 percent of patients with dSSc. Presence of these antibodies is also an independent risk factor towards development of progressive interstitial fibrosis. 2D ECHO and ECG should be done for cardiac evaluation and for determining pulmonary hypertension. Pulmonary function testing usually demonstrates decrease in timed vital capacity and forced expiratory flow, an early decrease in diffusion, and an increase in functional residual volume.

X-ray of the hands demonstrates the presence of acroosteolysis (decrease in soft tissue and resorption of

the tufts of the distal phalanges) along with bony erosions of distal interphalangeal and proximal interphalangeal joints. X-ray chest findings correlate poorly with pulmonary function. HRCT helps in identifying ground-glass opacification, subpleural micronodules, linear opacities, and “honeycombing”.⁴¹

JUVENILE LOCALIZED SCLERODERMA

Epidemiology

Juvenile localized scleroderma mainly involves localised areas of skin with few autoantibodies. It is more common than systemic sclerosis in childhood, by a ratio of at least 10:1⁴² with female-to-male ratio of 2.4:1. The mean age at onset of LS in the pediatric population is approximately 7 years.

Clinical Features

The onset of LS is subtle. It usually manifests as an area of localised erythema with induration. A localized form described as ‘en coup de sabre’ is usually associated with progressive hemifacial atrophy, ipsilateral uveitis, and various dental abnormalities.

Extra-cutaneous findings are more frequent in patients with linear scleroderma and consist essentially of arthritis, neurological findings or other autoimmune conditions. Seizures, headaches, behavioral changes, gastroesophageal reflux, uveitis, episcleritis and keratitis are few of the other findings.^{43,44}

Classification (Table 4)

Laboratory Results

The diagnosis of localized scleroderma is established by the clinical picture. No laboratory abnormality is diagnostic. However raised ESR, eosinophilia and hypergammaglobulinemia are quite characteristic of this disorder.

Rheumatoid factor is present in 25 to 40 percent of patients with ANA positivity of approximately 50 percent.⁴⁶ Antihistone antibodies, anti-Scl70 antibodies and anticardiolipin antibodies are few of the other antibodies found in this disorder.

Imaging in the form of MRI is useful only when CNS or eye involvement is suspected.

Outcome and Prognosis

Systemic Scleroderma

The outcome is usually poor and depends upon the extent of visceral involvement in dSSc. The prognosis can usually be divided into two groups one having a rapid development of internal organ failure leading to severe disability and eventually to death and the other group with slow, insidious course of the disease with lower mortality. The commonest causes of death

Table 4: The Mayo clinic classification of localized scleroderma⁴⁵

Plaque morphea

- Morphea en plaque
- Guttate morphea
- Atrophoderma of Pasini and Perini
- Keloid morphea
- [Lichen sclerosus et atrophicus]

Generalized morphea

Bullous morphea

Linear scleroderma

- Linear morphea
- En coup de sabre scleroderma
- Progressive hemifacial atrophy

Deep morphea

- Subcutaneous morphea
- Eosinophilic fasciitis
- Morphea profunda
- Disabling pansclerotic morphea

in children are related to the involvement of cardiac, renal, and pulmonary systems. Cardiomyopathy is a leading cause of early death. Patients with limited disease have a better prognosis.

Localized Scleroderma

The prognosis for LS is usually benign. The disease usually has an early inflammatory phase progressing to the extension of the lesion and finally stabilization and softening of the involved skin with increased pigmentation.⁴⁷

SJÖGREN'S SYNDROME

Sjogren's syndrome is probably the rarest of the connective diseases in childhood. Sjogren syndrome (SS) is defined as a chronic autoimmune disease characterized by inflammation of the exocrine glands principally the salivary and the lacrimal glands. SS may occur in 2 forms: primary (pSS), when the clinical manifestations of the syndrome are seen alone, and secondary (SSS), when associated with another autoimmune disease.

Clinical Criteria (Table 5)

Clinical Features with System Involvement

- Oral mucosal involvement-Xerostomia, difficulty in swallowing dry food, a change in taste, halitosis, increase in dental caries and recurrent parotitis.
- Ocular involvement: Keratoconjunctivitis sicca (KCS) manifested as dry eyes with sandy feeling.

Table 5: Proposed criteria for juvenile primary Sjögren's syndrome⁴⁸*Clinical symptoms*

- Oral (dry mouth, recurrent parotitis, or enlargement of parotid glands)
- Ocular (recurrent conjunctivitis without obvious allergic or infectious etiology, keratoconjunctivitis sicca)
- Other mucosal (recurrent vaginitis)
- Systemic (fever of unknown origin, noninflammatory arthralgias, hypokalemic paralysis, abdominal pain)

Immunological abnormalities (presence of at least 1 of: anti-SSA, anti-SSB, high titer ANA, RF)

Other laboratory abnormalities or additional investigations

- Biochemical (elevated serum amylase)
- Hematological (leucopenia, high ESR)
- Immunological (polyclonal hyperimmunoglobulinemia)
- Nephrological (renal tubular acidosis)
- Histological proof of lymphocytic infiltration of salivary glands or other organs
- Objective documentation of ocular dryness (Bengal red staining, Schirmer test)
- Objective documentation of parotid gland involvement (sialography)

Exclusion of all other autoimmune diseases

- Presence of 4 or more criteria

- Serologic testing for antibodies to Ro/SSA and La/SSB—considered the “hallmark” feature of this disease. ANA and positive RF are found in 70 percent of patients.

Course and Prognosis

Many patients with pSS have a benign course. The risk for B cell lymphoma as compared to pSS is very low.

MIXED CONNECTIVE TISSUE DISEASE**Epidemiology**

Mixed connective tissue disease (MCTD) is a syndrome where clinical features of multiple CTDs are present. It is one of the rarest of the CTD. The syndrome includes clinical features of rheumatoid arthritis (RA), scleroderma, SLE, and dermatomyositis in conjunction with a high antibody titer to an extractable nuclear antigen. MCTD is much more common in women with the median age of onset being approximately 11 years.

Classification Criteria (Table 6)*Clinical Features*

The early clinical features of MCTD are nonspecific and may consist of general malaise, arthralgias, myalgias, and low-grade fever. Almost any organ system can be involved in MCTD however, four clinical features that suggest the presence of MCTD are:

- *Other glandular involvement:* Dryness of the upper respiratory tract and rarely failure of the exocrine pancreatic function.
- Extra-glandular manifestations
 - Skin-Raynaud's phenomenon
 - *Pulmonary involvement:* Small airway obstructive disease and airway hyperactivity, interstitial lung disease
 - Renal Involvement—proximal and distal RTA, glomerulonephritis and interstitial nephritis.
 - Neurological involvement—Meningitis, myelopathy, cranial neuropathy, sensorimotor polyneuropathy, and mononeuritis multiplex.⁴⁹

Laboratory Examination

The evaluation of SS may consist of the following types of tests:

- Tests to confirm KCS—by a positive Schirmer test of wetting <5 mm in 5 min.
- Tests to quantify xerostomia: Salivary gland scintigraphy, parotid gland sialography or whole sialometry are frequently used.
- Salivary gland biopsy: Biopsy of the minor salivary glands of the lower lip demonstrating focal sialadenitis.

Table 6: Kasukawa criteria for mixed connective tissue disease⁵⁰*Common symptoms*

- Raynaud phenomenon
- Swollen fingers

*Anti-RNP Ab**Symptom**SLE*

- Polyarthritits
- Adenopathies
- Malar rash
- Pericarditis or pleuritis
- Leukopenia or thrombocytopenia

SSc

- Sclerodactyly
- Pulmonary fibrosis or restrictive changes in lung function or reduced DLCO
- Hypomotility or esophageal dilation

PM

- Muscle weakness
- Elevated muscle enzymes
- Myogenic signs on EMG

MCTD

If presence of at least 1 of the 2 common symptoms, anti-RNP antibodies, and the presence of at least 1 sign of at least 2 of the following connective tissue diseases: SLE, SSc, and PM.

- Raynaud phenomenon and swollen hands or puffy fingers.
- The absence of severe renal and central nervous system (CNS) disease
- More severe arthritis and the insidious onset of pulmonary hypertension
- Autoantibodies whose fine specificity is anti-U1 RNP, especially antibodies to the 68 Kd protein.

System Involvement

- Skin: Raynauds phenomenon, swollen digits, discoid plaques, malar rash, orogenital and buccal ulcerations, sicca complex
- Arthritis: Commonly seen, painful but predominantly non-erosive with RF positivity.
- Myositis: Rare but can present as low grade, insidious, and persistent inflammatory myopathy.
- Cardiac disease: Pancarditis of which pericarditis is commonest. Other abnormalities seen are right ventricular hypertrophy, right atrial enlargement, and inter-ventricular conduction defects
- Pulmonary involvement: Pulmonary hypertension, interstitial lung disease
- Renal disease: Usually absent
- Gastrointestinal disease: Disordered motility, duodenal bleeding, megacolon, pancreatitis, ascites, and protein losing enteropathy, primary biliary cirrhosis, portal hypertension and autoimmune hepatitis
- Central nervous system disease: Trigeminal (fifth cranial) nerve neuropathy, headaches and sensorineural hearing loss
- Hematologic: Low-grade anemia, hypergammaglobulinemia, leukopenia, thrombocytopenia, thrombotic thrombocytopenic purpura, Coombs positive hemolytic anemia, red cell aplasia

Laboratory Examination

Very high titers of ANAs are usually present. Anti-RNP antibodies in high titers have been the serological hallmark of MCTD. Antiphospholipid antibodies (including anticardiolipin antibodies and lupus anticoagulant) may be associated with pulmonary hypertension.⁵¹ Scleroderma-specific antibodies, including anticentromere, anti-Scl-70 (topoisomerase), and anti-PM-1 (Pm-Scl), are absent.

Other Investigations

- Chest X-ray: To assess for infiltrates, effusion, or cardiomegaly
- Echocardiography: For evaluation of pulmonary hypertension.
- Ultrasonography/CT scanning: Used to evaluate abdominal pain (indicated for evidence of serositis, pancreatitis, or visceral perforation related to vasculitis)
- MRI: Used to assess neuropsychiatric signs or symptoms
- Pulmonary function testing: To screen for declining diffusing capacity of lung for carbon monoxide
- ECG: To assess for myocardial ischemia and myocarditis.

Course of the Disease and Prognosis

Most patients with MCTD have a favorable outcome. Pulmonary hypertension is the most common disease-associated cause of death. Patients with severe Raynaud phenomena can develop ischemic ulcers and even outright gangrene of the fingers. MCTD tends to develop the widespread pain syndrome of fibromyalgia.

CONCLUSION

Though connective tissue diseases are not commonly seen by the general paediatrician they are important to diagnose early so that the child can be given the best possible outcome. The diseases have a protean manifestation and can present in several ways such that it is important to recognize a “disease pattern” and screen the patient appropriately with specific directed laboratory tests rather than “Panels” that serve to confuse more and helpless.

Urticaria

Amit Luthra

INTRODUCTION

Urticaria [or hives or nettle rash, according to the German term ‘Nesselsucht’, which focuses on the typical reactions following skin contact with the stinging nettle (*Urtica dioica*)] is a common problem, developing in 10 percent or more of individuals by adolescence and in 15 to 20 percent of individuals during a lifetime. Urticaria consists of the sudden onset of circumscribed, erythematous, edematous papules or plaques, often showing central clearing. Lesions vary from a few millimeters to centimeters in diameter, and they generally are annular or circular but can assume bizarre, irregular shapes.

Angioedema or Quincke’s edema or Giant Urticaria is a circumscribed, nodular swelling of deep cutaneous and subcutaneous or submucosal tissues, most commonly on the face, genitals, and mucous membranes.

In children, urticaria without angioedema is more frequent and occurs in 80 percent of those affected, both urticaria and angioedema occur in 15 percent, and angioedema alone occurs in 5 percent. About 50 percent of children experience urticaria for more than 1 year, with a mean duration of 16 months. Females predominate in acute and chronic forms of the disease.

Nearly all cases of urticaria in infants and most cases in children are acute (by definition restricted to an occurrence of no longer than 6 weeks). Chronic urticaria is present when lesions recur repeatedly over a period of more than 6 to 8 weeks.

Papular urticaria is a reaction to an arthropod bite, most commonly fleas, mites, bedbugs, gnats, mosquitoes, chiggers, or animal lice. The cutaneous reaction varies according to the extent of previous exposure to the same or related species of arthropod. After repeated bites, sensitivity develops, producing a pruritic papule within approximately 24 hours; this is the most common reaction seen in young children. With prolonged, repeated

exposure, a wheal develops within minutes after a bite, followed 24 hours later by papule formation; this combination of reactions is seen commonly in older children. By adolescence or adulthood, characteristically only a wheal forms, unaccompanied by the delayed papular reaction. Ultimately, as the individual becomes insensitive to the bites, there is no reaction.

ETIOLOGY

The cause of acute urticaria can be determined, on average, in approximately 50 to 75 percent of cases, whereas an identifiable cause can be determined in less than half of cases of chronic urticaria. Although causes of urticaria are similar for children and adults, age—dependent differences in etiology exist. In infants younger than 6 months, urticaria is due largely to cow’s milk allergy. Between age 6 months and 14 years, up to half of all cases of urticaria, particularly acute urticaria, are associated with infections. *Streptococcus pyogenes* is the most commonly associated infectious agent and has been associated with angioedema as well. Chronic urticaria is most often triggered by physical factors, but up to 45 percent of cases of chronic urticaria are also associated with infections.

Viral upper respiratory tract and gastrointestinal tract infections are the primary infectious triggers of acute urticaria in children.

Urticaria also can occur in association with infection with mycoplasmal, treponemal, rickettsial, fungal, or parasitic organisms, in Kawasaki disease, or in association with the infestation or bites of arthropods. The presence of parasitic infection is particularly likely in individuals with peripheral eosinophilia and elevated serum immunoglobulin (IgE) values.

Treatment of associated infections results in an improvement in urticaria in only a minority of patients. Furthermore, it is commonly unclear whether the

infectious agent, the therapeutic drug, or the combination was responsible for triggering the episode of urticaria. Aspirin, in particular, is known to exacerbate urticaria due to a variety of other causes, including infections. The medication that most commonly causes urticaria is penicillin and its derivatives; up to 25 percent of patients with chronic urticaria have antibodies to penicillin (Table 1).

PATHOGENESIS

Urticaria is due to an immediate hypersensitivity response, causing release of mediators from cutaneous mast cells and basophils as well as transudation of fluid from cutaneous blood vessels. Histamine is a primary mediator of urticaria and acts via both H₁ and H₂ receptors to produce vasodilation and altered vascular permeability.

Physical agents or drugs can produce urticaria by non-immunologic means. The most common immunologic mechanism for release of mediators is interaction of an

allergenic antigen (e.g. food or drug) with IgE bound to a basophil or mast cell, producing a type I hypersensitivity response. IgG autoantibodies can be responsible for urticaria in some patients by interacting with and causing cross linkage of adjacent IgE bound to a basophil or mast cell, producing a type I hypersensitivity response, suggesting that urticaria may be a manifestation of autoimmune mast cell disease. Complement activation with formation of the anaphylatoxins C3a, C4a, and C5a is an alternative immunologic mechanism for generation of urticaria.

Immune complex reactions can stimulate mediator release via the complement system. This process is particularly important in urticaria associated with hereditary angioedema, serum sickness, blood transfusion reactions, cryoglobulinemia, collagen vascular disease, urticarial vasculitis, and the urticaria like lesions of Henoch-Schönlein purpura. The mechanism of urticaria due to infectious agents is postulated to involve (1) the formation of immune complexes with activation of complement and

Table 1: Major infectious and noninfectious causes of urticaria in infants and children

<i>Infectious</i>	<i>Complement Activation</i>
<i>Bacteria</i>	Blood transfusion reactions, cryofibrinogenemia, cryoglobulinemia hereditary angioedema, hypocomplementemia, serum sickness, urticarial vasculitis.
<i>Borrelia burgdorferi, Escherichia coli, Neisseria gonorrhoeae, Neisseria meningitides, Pseudomonas aeruginosa, Shigella sonnei, Streptococcus pyogenes, Yersinia enterocolitica.</i>	<i>Contactants</i>
<i>Fungi</i>	Animal danders, caterpillars, chemicals, cosmetics, epoxy resins, fish, foods, medications, moths, nickel, parabens, saliva, water (i.e. aquagenic), wood dust.
<i>Candida albicans, Cladosporium spp, Coccidioides immitis, Histoplasma capsulatum, Candida glabrata, Trichophyton spp.</i>	<i>Drugs</i>
<i>Helminthes</i>	Acetylsalicylic acid, allopurinol, amoxicillin, barbiturates, cephalosporin antibiotics, tetracycline, codeine, curare, meperidine, morphine, nonsteroidal anti-inflammatory agents (e.g. indomethacin), penicillin, phenytoin, polymyxin B, procainamide, quinidine, radiocontrast materials, sulfa-derived antibiotics, sulfonylureas, thiamine, thiazides, zidovudine.
<i>Ancylostoma duodenale, Ascaris lumbricoides, Echinococcus spp, Enterobius vermicularis, Fasciola hepatica, Necator americanus, Onchocerca volvulus, Schistosoma spp, Strongyloides stercoralis, Toxocara canis, Trichinella spiralis, Trichobilharzia spp, (avian blood flukes), Wuchereria bancrofti</i>	<i>Food additives, preservatives and dyes</i>
<i>Mycoplasma</i>	Azo dyes (e.g. sunset yellow, tartrazine) butylhydroxyanisole butylhydroxytoluene, 4-hydroxybenzoic acid, sodium benzoate, sodium metabisulfite.
<i>Mycoplasma pneumoniae</i>	<i>Foods</i>
<i>Protozoa</i>	Chocolate, egg, fish, fresh berries, milk, nuts, peanuts, shellfish, tomatoes.
<i>Entamoeba histolytica, Giardia lamblia, Plasmodium spp., Trichomonas vaginalis.</i>	<i>Genetic conditions</i>
<i>Rickettsia</i>	C3b inactivator deficiency, erythropoietic protoporphyria, hereditary angioedema (CI esterase inhibitor deficiency).
<i>Coxiella burnetii.</i>	<i>Inhalant allergens</i>
<i>Treponeme</i>	Animal danders, mold spores, pollens
<i>Treponema pallidum</i>	<i>Physical factors</i>
<i>Viruses</i>	Aquagenic, cholinergic stimuli, including emotional stress (psychogenic) exercise, heat, cold, dermatographism, pressure, sunlight, sweating; vibration
Adenovirus, coxsackievirus A9, A16, B4, B5, Echovirus 11, Epstein-Barr virus, Hepatitis viruses A, B, C, Influenza B virus, Human immunodeficiency virus; Measles virus attenuated, Mumps virus, Respiratory syncytial virus.	<i>Systemic disease</i>
NONINFECTIOUS	Autoimmune thyroid disease, bullous pemphigoid, carcinomas, dermatomyositis, inflammatory bowel disease, juvenile rheumatoid arthritis, Kawasaki disease, leukemia, lupus erythematosus, lymphoma, polymyositis, rheumatic fever, Sjögren's disease.
<i>Arthropod bites</i>	
Ants, bedbugs, bees, body lice, caterpillars, fleas, chiggers), mosquitoes, scabies mites, scorpions, spiders, wasps.	

release of anaphylatoxins or (2) the development of IgE antibodies to microbial antigens.

Clinical Manifestations

Circumscribed, raised erythematous, usually pruritic, evanescent areas of edema that involve the superficial portion of the dermis are known as urticaria; when the edematous process extends into the deep dermis and/or subcutaneous and submucosal layers, it is known as angioedema. The individual lesions of urticaria arise suddenly, rarely persist longer than 24 to 48 hours, and may continue to recur for indefinite periods.

Episodes of lesions of less than 6 to 8 weeks duration are considered acute, whereas those persisting longer are termed chronic. Headache, dizziness, the sensation of a lump in the throat, hoarseness, wheezing, shortness of breath, nausea, vomiting, abdominal pain, diarrhea, and arthralgias may occur as concomitant systemic manifestations of urticaria and angioedema.

Immunological IgE and IgE Receptor—Dependent Urticaria/Angioedema

Episodes of acute urticaria/angioedema occurring in individuals with a personal or family history of asthma, rhinitis, or eczema are presumed to be IgE dependent. In clinical practice, however, urticaria/angioedema infrequently accompanies an exacerbation of asthma, rhinitis, or eczema. The prevalence of chronic urticaria/angioedema is not increased in atopic individuals.

Specific Antigen Sensitivity

Common examples of specific antigens provoking urticaria/angioedema include foods, such as shellfish, nuts and chocolate; drugs and therapeutic agents, notably penicillin; aeroallergens; and Hymenoptera venom. Urticaria in patients with helminthic infestations has also been attributed to IgE-dependent process; however, proof of this relationship is often lacking.

Physical Urticaria/Angioedema

Dermographism is the most common form of physical urticaria. It appears as a linear wheal with a flare at a site in which the skin was briskly stroked with a firm object. A transient wheal appears rapidly and usually fades within 30 minutes. The clinically normal skin may be pruritic. Dermographism associated with substantial degrees of pruritus has been referred to as symptomatic dermographism. The peak prevalence occurs in the second and third decades.

Delayed dermographism develops 3 to 6 hours after stimulation, either with or without an immediate reaction, and lasts 24 to 48 hours. The clinical eruption is composed of linear red nodules. It may be associated with delayed

pressure urticaria. Cold dependent dermographism may occur only after cold exposure. A rare form that develops as punctuate wheals is known as cholinergic dermographism.

Pressure Urticaria

Pressure urticaria appears as erythematous, deep local swellings, often painful that arise from 0.5 to 6 hours after constant pressure has been applied to the skin. The peak prevalence occurs in the third decade. Pressure urticaria may be associated with fever, chills, and arthralgias as well as with an elevated erythrocyte sedimentation rate and leukocytosis. Spontaneous episodes are elicited under shoulder straps after manual labor.

Immediate pressure urticaria is a rare idiopathic disorder. It has also been described in patients with the hypereosinophilic syndrome.

Vibratory Angioedema

Vibratory angioedema may occur as an acquired idiopathic disorder, in association with cholinergic urticaria, or after several years of occupational exposure to vibration.

Cold Induced Urticaria

There are both acquired and inherited forms of cold induced urticaria/angioedema. The acquired forms are more common. Idiopathic, or primary, acquired cold induced urticaria may be associated with headache, wheezing, shortness of breath, hypotension, and syncope. Attacks occur within minutes after the appropriate exposures that include cold foods or liquids, the appearance of a wheal after the application of ice has been called a diagnostic cold contact test. If the entire body is cooled, as in swimming, hypotension and syncope, which is a potentially lethal event, may occur.

Solar Urticaria

Pruritus, erythema, wheals, and occasionally angioedema with bronchospasm and syncope develop within minutes after exposure to the sun or artificial light sources. Although this disorder may be associated with systemic lupus erythematosus or erythropoietic protoporphyria, it is usually idiopathic.

Cholinergic Urticaria

Cholinergic urticaria, also known as generalized heat urticaria, develops after an increase in core body temperature, such as during a warm bath or shower, exercise, or episodes of pyrexia. The eruption appears as distinctive, pruritic, small, 1 to 2 mm wheals that are surrounded by large areas of erythema. Systemic features may include dizziness, headache, wheezing, shortness of breath, nausea, vomiting, and diarrhea.

Heat Urticaria

Local heat urticaria is a rare form of urticaria in which wheals develop within minutes after exposure to locally applied heat.

Exercise—Induced Anaphylaxis

Exercise—induced anaphylaxis is a clinical symptom complex consisting of pruritus, urticaria, angioedema (cutaneous, laryngeal and intestinal) and syncope that is distinct from cholinergic urticaria.

Adrenergic Urticaria

Adrenergic urticaria occurs as wheals surrounded by a white halo that develop during emotional stress. The lesions can be elicited by the intracutaneous injection of noradrenaline.

Aquagenic Urticaria and Aquagenic Pruritus

Contact of the skin with water of any temperature may result in pruritus alone or, more rarely, urticaria. The eruption consists of small wheals reminiscent of cholinergic urticaria.

Patients with aquagenic pruritus should be followed for the emergence of a hematologic disorder.

Contact Urticaria

Urticaria may occur after direct contact with a variety of substances. It may be immunologic (IgE mediated) or nonimmunologic. The transient eruption appears within minutes and, when IgE – mediated may be associated with systemic manifestations. Proteins from latex products are becoming a prominent cause of IgE mediated contact urticaria. The risk group is dominated by biomedical workers and individuals with frequent contact with latex, such as children with spina bifida.

Papular Urticaria

It occurs as episodic, symmetrically distributed, pruritic, urticarial papules that are episodic, symmetrically distributed, pruritic, urticarial papules that are caused by bites of insects such as mosquitoes, fleas, and bedbugs. This condition is mainly seen in childhood.

DIAGNOSIS

Diagnosis is established from the history and clinical characteristics. Non-urticarial conditions that can have an urticarial phase include erythema toxicum neonatorum, erythema multiforme, erythema nodosum, anaphylactoid purpura, Kawasaki disease, diffuse cutaneous mastocytosis, and bullous pemphigoid.

Biopsy can be helpful in equivocal cases or when urticarial vasculitis is suspected. Biopsy of an urticarial lesion

is expected to show dermal edema, dilation of blood and lymphatic vessels, and a sparse perivascular mononuclear infiltrate with variable numbers of eosinophils. Urticarial vasculitis is characterized by swelling of endothelial cells and fibrinoid necrosis of postcapillary venules, red blood cell extravasation, leukocytoclasia (i.e. fragmentation of neutrophil nuclei) and perivascular and vascular inflammation with neutrophils.

Diagnostic tests in a child with acute urticaria are performed when findings other than urticaria suggest a specific etiology (e.g. streptococcal pharyngitis, bacterial enteritis). In chronic urticaria, laboratory evaluation, even if it is thorough, is unrevealing unless a specific allergen (food, drug, contactant, inhalant), infection, infestation, or underlying systemic disease is suspected. If a physical cause for urticaria is identified, additional testing is unnecessary. If angioedema is a prominent, consistent feature, the patient should be tested for hereditary deficiency of C1 esterase inhibitor by measuring plasma C4 complement concentration. Useful tests for identifying a cause of urticaria are:

- A complete count,
- Throat swab collection for *S. pyogenes* culture or anti-streptolysin O titer,
- Epstein-Barr virus serologic test,
- Serum hepatic enzyme measurements,
- Serologic tests for hepatitis viruses,
- Urinalysis and urine culture,
- Vaginal smear for *Candida* and *Trichomonas*,
- Stool examination for ova and parasites, and
- Radiographs of the sinuses and teeth.

MANAGEMENT

Infectious agents of acute and chronic urticaria should be identified and treated, when possible, and stimuli of physical urticaria, such as heat, cold, exercise, and emotional stress, should be minimized.

The most successful symptomatic approach to treatment of urticaria with medication is blockage of the effect of histamine at its receptor on cutaneous blood vessels. Regimens include therapies with H₁ antihistamines, combination H₁ and H₂ receptor blockers, and tricyclic antidepressants. Antihistamines that block H₂ receptors are the mainstay of treatment for urticaria. Hydroxyzine hydrochloride is the most effective of the classic H₁ antihistamines for suppression of the wheal and flare response, pruritus, dermatographism, and cholinergic urticaria. Whereas cyproheptadine is the drug of choice for cold induced urticaria. For patients who experience excessive sedation or mucosal dryness, the newer, nonsedating H₁ antihistamines, such as fexofenadine, loratadine, astemizole, and cetirizine, are effective alternatives. These agents have been shown to be comparable in efficacy with hydroxyzine and one another for treatment of urticaria.

The therapeutic response to the H₁ antihistamines can be improved with the addition of an H₂ receptor-blocking agent, such as cimetidine or ranitidine.

The dosage of antihistamines is often more important than the particular agent. Antihistamine therapy should be initiated at the upper end of the recommended dosage range and then gradually increased as needed until symptoms are relieved or side effects, particularly sedation, become prohibitive. In general, the dosage should not exceed approximately twice that recommended by the manufacturer. The current European Academy of Allergology and Clinical Immunology/Global Allergy and Asthma European Network/European Dermatology Forum (EAACI/GA LEN/EDF) guidelines call for up dosing of nonsedating antihistamines (up to four times the standard dose) in urticaria patients who do not respond satisfactorily to the standard doses. The effectiveness of antihistamines in children, particularly those with dermatographism, appears to be produced, at least in part, by their sedative action. Bothersome drowsiness can be minimized by administering most of the daily dose just before bedtime. Once urticaria has been adequately controlled, the dose of antihistamine should be tapered gradually, rather than stopped abruptly, to minimize the likelihood of a recurrence.

Topical corticosteroid agents are ineffective in urticaria, and systemic corticosteroids are rarely indicated in children, except in severe unremitting cases, especially those associated with asthma, laryngeal edema, or circulatory instability or when angioedema is particularly severe on the face.

Pediatric Dentistry: An Update

Arindam Dutta

INTRODUCTION

The science and art of the dental management of the child patient is an entire discipline in itself and encompasses not only the treatment of dental disease but also places an equal emphasis on preventive aspects, monitoring the developing dentition and to inculcate a positive attitude toward dentistry. According to American Academy of Pediatric Dentistry (AAPD), *pediatric dentistry* is an age-defined specialty that provides both primary and comprehensive preventive and therapeutic oral health care for infants and children through adolescence, including those with special health care needs.¹ Boucher's Clinical Dental Terminology explains *Pedodontics* as a branch of dentistry; it includes training the child to accept dentistry; the prevention, detection, restoration and maintenance of the deciduous and permanent dentition; applying preventive measures for periodontal therapy and dental caries; prevention, interception and correction of various errors of occlusion.² As a specialty, *Pedodontics* was born in 1923 when 14 Detroit dentists led by Dr Walter McBride formed the Paediatric Study Club. This was followed by the formation of the American Society for Promotion of Children's Dentistry in 1927 and the publication of the *Journal of Dentistry for Children* in 1928. In India, the Indian Society for Paedodontics and Preventive Dentistry was established in 1928 and Dr Vacher is considered to be the Father of *Pedodontics* in our country.

This chapter discusses some of the most pertinent aspects of pediatric dentistry of relevance to the pediatrician. These have been included under the headings of the First Dental Visit, Dental Caries, Dental Trauma with special emphasis on Tooth Avulsion, Orthodontic Treatment, Strategies to Manage the Anxious Child, Extractions, and Oral Habits.

FIRST DENTAL VISIT

There seems to be a lot of confusion amongst parents, pediatricians, and dentists about the correct timing for the first dental visit. Many dentists may tell parents not to bring children to their practice before they have all their primary teeth (age two or three), sometimes even recommending to wait until age 6. Under unfavorable circumstances, delay of dental care can lead to catastrophic disease progression that is not in the best interest of the child. The AAPD recommends an initial postnatal oral evaluation within six months of the eruption of the first primary tooth and no later than 12 months of age.³ At this examination visit the dentist should record a thorough medical and dental history. Parents should be prepared to review the prenatal, perinatal, and postnatal period of their child's development. The oral examination at this early age is usually accomplished with the parent present in the office. It is most often only a visual examination. The child patient may be sitting in the parent's lap with the head in the dentist's lap (knee-to-knee position). One important aspect of this visit is to discuss the child's risk of developing oral and dental disease. Based on this assessment, the dentist will determine the appropriate recall interval for the next dental visit. This will not be more than 12 months for all individuals under 18 years of age.⁴ In high-risk cases, this may be as early as three months as dental decay in children can progress very rapidly. The dentist will also evaluate the child's oral and dental development, need for fluoride supplementation and discuss non-nutritive habits (finger sucking, pacifier), injury prevention, oral hygiene (including toothbrushing), and effects of diet on the dentition. At this visit, the parents should also be informed of the tentative eruption schedule of the child's primary dentition. Table 1 lists the chronology of human dentition.⁵

Table 1: Chronology of the human dentition⁵

Premature tooth exfoliation has been reported to be associated with some systemic diseases, such as hypophosphatasia, Papillon Le Fevere syndrome, cyclic neutropenia, Chediak Higashi syndrome, histiocytosis X and prepubertal periodontitis.⁶

TEETHING

Teething in the infant has been traditionally associated with several local and systemic disturbances. The

information pertaining to teething is very often based on parental observations. It is also difficult to separate the signs and symptoms of teething from the normal psychological and physiological changes, such as drooling and wakefulness. Teething is considered uncomfortable for the child, and signs and symptoms include swollen gums that are tender to palpation, drooling, chewing fingers and other inanimate objects, irritability, restlessness and night crying. Other signs commonly attributed to teething, such as diarrhea, cough, ear rubbing, rashes, fever

and convulsions, have not been found to have any relationship to teething. 224 normal children were studied for the association of 18 disturbances with the eruption of the deciduous teeth.⁷ Irritability, night crying, drooling, poor appetite, circumoral rash and inflammation of the gums were common findings. Tasanen studied teething infants in North Finland and showed that tooth eruption bore no relation to infection, diarrhea, fever, rash, convulsions, sleep disturbance, cough or ear rubbing.⁸ Teething was associated with daytime restlessness, loss of appetite, hand sucking, drooling and some appetite loss. In a 1975 study of perceptions of primary care pediatricians in Philadelphia, only five believed that teething was not responsible for symptoms such as irritability, eating problems, wakefulness and rashes.⁹ Eighteen felt that teething could be responsible for temperatures up to 39.4°C. Illingworth suggested that in 6 to 12-month-old infants, much of the evening and night-time crying that is attributed to teething may be due to bad habit formation: infants of this age have discovered that if they cry at night, they will be picked up, played with and given a thoroughly enjoyable time.¹⁰ Teething complaints are confined almost exclusively to the eruption of the deciduous dentition. In 1990, Wray suggested that the current understanding was that teething coincides with the stage of development when active immunity is struggling to take over from the waning passive immunity of the mother. This often results in ENT or gastrointestinal infection in a child with an obvious oral fixation who will naturally suck or chew their fingers.¹¹ More recently, a viral infection (herpes simplex virus) etiology has been proposed and investigated.¹²

Various treatments are now advocated for the relief of the discomfort or pain associated with teething. Rubbing substances into the gums and chewing on hard objects are still extremely common. Gum lancing is now relegated to history, although surgical removal of eruption cysts overlying a deciduous tooth may still be carried out when indicated. Chewing on clean, hard, cool objects will give relief from soreness and items, such as chilled teething rings and rattles, cold wet flannels, chilled hard vegetables, such as carrots and cucumber and an ice cube tied in a cloth have been tried. Teething biscuits and rusks are not suitable as they can promote tooth decay. In 1998, Government Safety Regulators in the United States asked manufacturers to stop using a softening chemical (disononyl phthalate) known to be a carcinogen in baby rattles and teething toys as it tends to leach out from the product. There have been no reported cases of phthalate related cancer in infants using teething products. The use of chilled topical preparations in gel form remains popular. Lignocaine-containing products have been shown to be more effective than similar, control preparations without lignocaine. However, many authorities advise that these gels are largely insufficient to treat the condition when used alone, due to the rapid washing away from the site

of discomfort. A sugar-free paracetamol suspension may be used for supplementation and is useful for its analgesic and antipyretic effects.

DENTAL CARIES

Dental caries is perhaps one of the most prevalent diseases affecting the human race. There are practically no geographic regions in the world that do not exhibit some evidence of dental caries. It affects persons of both sexes, in all races, socioeconomic strata and every age group.

Dental caries has been defined as an infectious, microbial multifactorial disease of the hard tissues of the teeth resulting in demineralization of the inorganic components and dissolution of the organic components.

Ostrom (1980) has defined caries as a process of enamel or dentin dissolution that is caused by microbial action at the tooth surface and is mediated by physiochemical flow of water dissolved ions.¹³ Hume (1993) states that caries is essentially a progressive loss of acid dissolution of the apatite component of the enamel, dentin and cementum of the tooth.

Site

Caries affects the occlusal surfaces of posterior teeth (pits and fissures of molars and premolars), the proximal and cervical areas as well as the roots of all teeth. It may also be found on the lingual and palatal surfaces of the anterior teeth as well as the maxillary posterior dentition. In its most initial form, it presents as a white spot lesion in enamel. This can be seen as a chalky opaque surface when a tooth has been dried out and is indicative of an initial mineral loss. In its most severe form, caries can affect all surfaces of the tooth. Figure 1 shows dental decay in the upper incisors and Figure 2 shows dental caries in the lower posterior dentition of a child. Figure 3 is a figurative representation of dental caries on a model posterior tooth (sagittal section) at different locations on the tooth and at varying depths in enamel and dentine.

Fig. 1: Dental caries in the maxillary anterior dentition
(For color version see plate 18)

Fig. 2: Dental caries in the lower posterior dentition
(For color version see plate 18)

Fig. 3: Sagittal section of a tooth model showing decayed area occlusally and proximally (For color version see plate 18)

Symptoms

Chronic caries can often be asymptomatic. As a slowly progressing lesion, it may produce tooth destruction over a period of time without causing any overt discomfort for the child. However, caries would usually be associated with some form of sensitivity to hot and cold foods and beverages when it extends into dentine. If the pulp of the tooth also becomes involved, it would be likely for the child to suffer from variable amounts of pain—it could be an ache that is brought on when the child eats or drinks to an ache that is constant, throbbing, and unbearable in nature.

Prevalence of Caries

Dental caries is not a recent disease entity. Its existence has been demonstrated from the times of the prehistoric man, such as the Pithecanthropus or the Java Man. The current global epidemiology of caries shows a wide difference between the developed and the third world countries, primarily due to the lack of infrastructural support. Thus sub Saharan Africa, some regions of South America and underdeveloped Asia present with high caries experience as dental care facilities are almost non-existent whereas the developing world presents a slightly better condition. There is an increase in the amount of refined carbohydrate consumption in the developing nations but dental services are only concentrated around urban centers. The interplay of these two factors has resulted in an increased caries incidence in countries, such as India, Chile, Uganda and Thailand. The developed world has an abundance of preventive, interceptive as well as curative options, which has led to a steady decline in caries indices such as the Decayed Missing Filled Tooth index (DMFT) over a period of time.

Dental Caries in India is consistently increasing in prevalence and severity especially in children, with almost 70 to 80 percent suffering from this disease. The First

National Oral Health Survey was planned in 1984 by the Indian Dental Association found regional differences with an increase in caries incidence being noted in all the northern states barring Punjab in the age group of 5 to 6 years. However in the age group of 15 years, caries was shown to have declined. The eastern part of the country showed an increase in caries in both the deciduous as well as permanent dentitions, as did the southern states (except a few pocket areas, such as the Dakshin Kannada district). The western region, Bombay showed a slight decrease, but this too was well above the WHO goals.¹⁴ In the United Kingdom, the National Children's Dental Health Survey in 2003 revealed that the DMFT at age 12 (the key age at which children are internationally compared) was 0.7 in England, which is the lowest since records were first established. In the same survey, it was also found that 57 percent of 5 year olds, 62 percent of 12 year olds and 50 percent of 15 year olds in the UK had never experienced dental decay or required dental restorations.¹⁵ In the United States, National Health and Nutrition Examination surveys (NHANES) and National Institute of Dental Research Surveys has shown that caries prevalence in the permanent dentition of children between ages 5 and 17 years, at least half the children were free from decay; in the 1970s only a quarter were free from decay. However, unlike the dramatic decrease in prevalence for the permanent dentition, the primary dentition caries rates have remained unchanged among children from low income families. NHANES III measured caries in primary incisors of 1 year old children and found 2 percent incisors with an abnormal appearance suggestive of decay using the 'lift the lip' technique.¹⁶

Mechanism of Caries Formation

Cariogenic Bacteria + Suitable local substrate = Organic acids

Organic Acids in Plaque + Tooth mineral = Loss of enamel

Demineralized Tooth (Dentin) + Bacterial Proteolytic Enzymes = Cavitation¹⁷

Caries is a multifactorial disease, which requires an interaction between a susceptible host, i.e. the tooth, a microflora with cariogenic potential and a suitable local substrate to meet the requirements of the pathogenic flora. Newbrun added a dimension of time factor to the above three factors and termed it the caries tetralogy.^{18,19} This is diagrammatically represented in Figure 4.

The pathogenic flora includes *Streptococcus mutans*, which is perhaps the most important pathogen in the initiation of caries.²⁰⁻²⁴ Other microorganisms like *Lactobacillus acidophilus*, *Lactobacillus casei*, *Actinomyces viscosus*, *Prevotella*, *Selenomonas*, *Dialister*, *Fusobacterium nucleatum*, *Eubacterium*, *Lachnospiraceae*, *Olsenella*, *Bifidobacterium*, *Propionibacterium*, *Pseudoramibacteria lactolyticus* and other species of *Streptococcus* such as *S. mitis*, *S. mitior*, *S. salivarius* also play a role in the progression of caries.^{17,25} The microorganisms produce extracellular polysaccharide from either glucose or sucrose using an enzyme glucosyl transferase. In the process, organic acids are generated as by-products of the reaction. These are localized on to the tooth structure and held within plaque. The acid then produces an ionic imbalance between the tooth surface and its immediate environment. The constant homeostasis of Re- and demineralization is, therefore, disturbed and weighs in favor of the latter. This initiates the caries process.²⁶

Nursing Caries and Rampant Caries

Winter (1966) has described it as a lesion of acute onset involving many or all of the erupted teeth, rapidly destroying coronal tissue, often on surfaces normally immune to decay, and leading to early involvement of the dental pulp.²⁷

Numerous reports by pediatricians and pedodontists describe a rapidly progressing type of dental caries

that affects the primary teeth of children, usually during the first two years of life and as early as the first year.¹⁹ A unique caries pattern can be identified with the four maxillary incisors being affected first because of their position in the mouth as to be most frequently bathed by a feeding formula. Because of this appearance, it has also been termed labial caries.²⁸ If unchecked, the decay may extend to the maxillary and mandibular molars. Initially, the lower anterior teeth may not be involved because of the protective environment of the mandibular salivary secretions and the cleansing action of the tongue muscles.^{17,29} Should the lesions arrest, they pigment to a black or dark brown color and this has been termed melanodontic infantile.³⁰

Over the past few decades this clinical entity has been variously termed as rampant caries,²⁷ nursing bottle caries, nursing bottle mouth,³¹ bottle-mouth caries,³² nursing bottle caries,³³ baby bottle caries,³⁴ nursing bottle syndrome,³⁵ baby bottle tooth decay and nursing caries.¹⁹ However, of late, and by international consensus, all such clinical entities have been listed as "early childhood caries", a term that represents a complex disease involving maxillary primary incisors within a month after eruption and that spreads rapidly to involve other primary teeth.^{36,37} The classification for early childhood caries (ECC) is presented in Table 2.³⁷ The role of parental/ caregiver stress has also been evaluated in children with ECC.³⁸

Infancy caries is most often seen in children with an unusual dietary history such as the addition of syrup, honey or sucrose to the formula or the use of pacifier

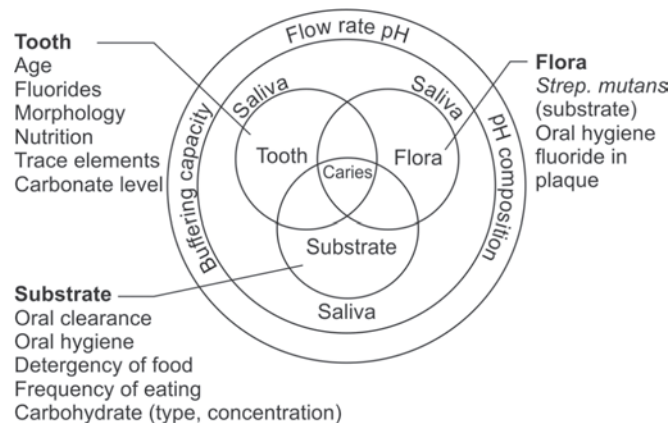

Fig. 4: Factors in caries development

Table 2: Classification of early childhood caries

Type I ECC (Mild to moderate)	<p>Cariou lesions involving the molars and incisors.</p> <p>Seen in 2 to 5 years.</p> <p>Cause is usually a combination of cariogenic semisolid or solid food and lack of oral hygiene</p> <p>Number of affected teeth usually increases as the cariogenic challenge persists.</p>
Type II ECC (Moderate to severe)	<p>Labiolingual carious lesion affecting the maxillary incisors with or without molar caries, depending on age.</p> <p>Seen soon after the first tooth erupts.</p> <p>Unaffected mandibular incisors.</p> <p>Cause is usually inappropriate use of feeding bottle or at will-breastfeeding or combination of both, poor oral hygiene</p>
Type III ECC (Severe)	<p>Cariou lesions involve almost all the teeth, including mandibular incisors.</p> <p>Usually seen in 3 to 5 years of age.</p> <p>Cause is a combination of factors and a poor oral hygiene.</p> <p>Rampant in nature and involves immune tooth surfaces.</p>

dipped in honey or other sweeteners.^{19,27,35} Initial etiological agents were thought to be the sucking of the comforter or the pacifier which was coated with a sweetening agent, namely sweetened malt, honey, sugar, jam or aniseed syrup. Rampant caries in young children was very common after the introduction of syrups in the United Kingdom. Prolonged use of the comforter feeding bottles containing milk and sugar, fruit juice and sugar, fruit syrup or sugared water increased the viscosity of the fluid and the time required to draw the formula through the nipple.²⁷ The hollow 'feeder' has also been implicated. This has a reservoir behind the teat that can hold 10 ml of fluid. Manufacturer's encourage parents to place honey, sugar, syrup into this area.

In addition to an increase in caries rates due to the use of improper formula in bottle-feeding, it has also been reported that prolonged and unrestricted night time breast feeding can result in increased caries rate (Preston et al 1977). The stagnation of the milk about the neck of anterior teeth and the fermentation of the disaccharide lactose, found in milk, contribute to the carious process. Under usual feeding regimens neither bottle nor breast milk predispose to caries. Only a prolonged and unrestricted bottle or breast milk-feeding regimen may play a role in caries production. Of more significance is the addition of caloric sweeteners to formulas.

Management involves parental counseling regarding the dietary habits of the infant and toddler, arrest and control of carious process, institution of preventive practices followed by restoration and rehabilitation of the dentition.

ODONTOGENIC INFECTIONS AND CARIES

The progression of caries is from the enamel of the crown of the tooth through to dentin and then to the pulp space of the tooth. Once the microbes from the carious lesion have invaded the pulp of the tooth, they or their toxins progress through the root of the tooth and the apical foramen (at the tip of the root) into the surrounding periodontal ligament and thence into the alveolus. In a chronic case, they may produce localized changes in bone that may result in the formation of a periapical granuloma or a periapical cyst. Sometimes, it can lead to the development of an abscess as well. If chronic, it usually drains through a sinus tract in to the mouth along the attached gingiva. At other times, it may lead to the formation of an acute abscess with concomitant intraoral swelling. A rapid spread of toxins through the facial spaces may lead to the development of cellulitis with a grossly enlarged and swollen face or neck, depending on location of the tooth. Institution of antibiotic therapy may be warranted in such instances with subsequent treatment involving drainage through the root canal of the tooth or an extraction of the offending tooth. Sometimes, as a swelling localizes,

intraoral drainage may be established with relevant incision and drainage methods.

Caries Risk Assessment

It is important to risk assess the patient in order to accurately quantitate a person's disease susceptibility and allow for preventive measures. Even though caries-risk data in dentistry are not sufficient to quantitate the models, the process of determining risk should be a component in the clinical decision making process. According to the American Academy of Paediatric Dentistry, Risk assessment:

- Fosters the treatment of the disease process instead of treating the outcome of the disease
- Gives an understanding of the disease factors for a specific patient and aids in individualizing preventive discussions
- Individualizes, selects, and determines frequency of preventive and restorative treatment for a patient
- Anticipates caries progression or stabilization.³⁹

Caries-risk assessment models currently involve a combination of factors including diet, fluoride exposure, a susceptible host, and microflora that interplay with a variety of social, cultural, and behavioral factors. Caries risk assessment is the determination of the likelihood of the incidence of caries (i.e. the number of new cavitated or incipient lesions) during a certain time period or the likelihood that there will be a change in the size or activity of lesions already present. With the ability to detect caries in its earliest stages (i.e. white spot lesions), health care providers can help prevent cavitation.

Risk assessment tools can aid in the identification of reliable predictors and allow dental practitioners, physicians, and other nondental health care providers to become more actively involved in identifying and referring high-risk children. Table 3 incorporates available evidence into practical tools to assist physicians, and other nondental health care providers in assessing levels of risk for caries development in infants and young children. As new evidence emerges, such tools can be refined to provide greater predictability of caries in children prior to disease initiation. Furthermore, the evolution of caries-risk assessment tools and protocols can assist in providing evidence for and justifying periodicity of services.

Detection of Dental Caries

Some of the traditional methods of caries detection have included a visual and tactile examination of the dentition.⁴⁰ Carious areas appear brownish-black in chronic caries to yellowish white in more acute and rapidly progressing lesions. Invariably, these would either be leathery or soft in consistency. Depending on the site of decay, it could also appear as a greyish hue just below the intact surface of enamel, the carious process itself having progressed in to dentine through a small pit on the occlusal surface of

Table 3: Caries-risk assessment form for 0-3-year-olds
(For physicians and other non-dental health care providers)
(From the American Academy of Paediatric Dentistry)

<i>Factors</i>	<i>High-risk</i>	<i>Moderate risk</i>	<i>Protective</i>
<i>Biological</i>			
Mother/primary caregiver has active cavities	Yes		
Parent/caregiver has low socioeconomic status	Yes		
Child has >3 between meal sugar-containing snacks or beverages per day	Yes		
Child is put to bed with a bottle containing natural or added sugar	Yes		
Child has special healthcare needs		Yes	
Child is a recent immigrant		Yes	
<i>Protective</i>			
Child receives optimally-fluoridated drinking water or fluoride supplements			Yes
Child has teeth brushed daily with fluoridated toothpaste			Yes
Child receives topical fluoride from health professional			Yes
Child has dental home/regular dental care			Yes
<i>Clinical findings</i>			
Child has white spot lesions or enamel defects	Yes		
Child has visible cavities or fillings	Yes		
Child has plaque on teeth		Yes	

Circling those conditions that apply to a specific patient helps the healthcare worker and parent understand the factors that contribute to or protect from caries. Risk assessment categorization of low, moderate, or high is based on preponderance of factors for the individual. However, clinical judgment may justify the use of one factor (e.g. frequent exposure to sugar containing snacks or beverages, visible cavities) in determining overall risk.

Overall assessment of the child's dental caries risk: High ☐ Moderate ☐ Low ☐

enamel. A variant of the tactile method uses dental floss in between teeth. The shredding of floss upon withdrawal is indicative of a possible area of proximal decay. Further diagnostic methods include radiographic examination.⁴¹ A variety of radiographs may be utilized, though the horizontal bitewing intraoral views are the most reliable. These are especially useful for the detection of proximal decay at sites that are not clinically visible. Other radiographs such as the long cone periapical intraoral view are beneficial for the assessment of the crown and root structures of the tooth, including the area of bone in the vicinity of the root tip. This radiograph will also provide information regarding any changes in the bony architecture at the periapex of the tooth. A dental panoramic tomogram provides a more generalized view of the dentition and perioral tissues. Gross carious lesions can be appreciated but detail of carious radiolucencies cannot be appreciated in the anterior teeth, especially the mandibular anteriors, due to their overlap with the cervical spine area. Modern techniques of caries detection have also been investigated and introduced to the market, such as quantitative

light induced fluorescence,⁴² laser fluorescence (available as Diagnodent, KaVo, Biberach, Germany. Use is shown in Figure 5)⁴³ and electrical conductance and resistance measurements.⁴⁴ Some experimental techniques of caries detection have been reported, such as multiphoton imaging, infrared thermography, infrared fluorescence, and optical coherence tomography.⁴⁵

Preventive Approach for Dental Caries

One of the simplest ways of preventing the development of dental decay is the institution of good oral hygiene measures from birth itself. Before the eruption of teeth, oral hygiene can be maintained by cleaning the gum pads with a moist cotton gauze after feeding. The mainstay of oral hygiene measures for children is toothbrushing once the first tooth erupts. The recommended frequency for brushing is twice a day, for at least two minutes at each brushing exposure. A smear of tooth paste may be applied to the brush for very young children below the age of 2 years and a pea sized tooth paste amount used for children over this age.⁴⁶ The Fones technique of tooth brushing

Fig. 5: Diagnodent uses laser fluorescence for caries detection

has been recommended and involves circular motions of brush movement on teeth. In areas that do not receive fluoridated water, the child may be encouraged to spit out the toothpaste at the end of brushing without rinsing the mouth to help retain fluoride around teeth and thus prolong its period of contact with dental hard tissues. Special kids' toothpastes are available that have the appropriate fluoride levels of around 500 ppm.

Fluoride's role in decreasing the prevalence of caries has been well accepted for many years. However, the beliefs about fluoride have changed. It is now established that the presence of fluoride in and on enamel surface is the key to the effectiveness of fluoride.⁴⁷ Fluoride is incorporated throughout the tooth crown formation during development of the tooth. In the pre-eruptive phase, fluorides have also shown to make the pits and fissures on the occlusal surfaces of molars and premolars shallower, thereby making them more amenable to oral hygiene procedures.^{48,49} In the post-eruptive phase also, fluoride continues to enter the enamel surface causing crystals

to change from predominantly carbonate apatite and hydroxyapatite to fluorapatite and fluor-hydroxyapatite crystals. These fluoride rich crystals are less acid soluble than the original enamel apatite.⁵⁰ Fluorides also possess the capacity to aid in the remineralization of incipient demineralization of tooth structure where cavitation has not taken place yet.⁵¹ The re-growth by fluoride incorporation chemically forms new crystals that are larger and more acid resistant and contain a higher concentration of fluoride.⁵² Fluorides can be administered through systemic as well as topical application.^{53,54} The various routes of administration are demonstrated in Figure 6.^{53,55} The topical route is considered more efficacious.^{54,56}

The anatomy of the posterior dentition is complex. The occlusal (biting) surface of the molars features many pits and fissures in enamel that are potential traps for plaque and microorganisms that could lead to the development of decay. The recognition of such susceptible areas of the surface of teeth during a regular dental examination is important. As a preventive measure, such areas could be preventatively sealed off using a flowable, often light cured material known as pit and fissure sealant. In the most conservative form of treatment using pit and fissure sealants, the tooth is not prepared with the drill at all and the pit and fissure sealant is retained onto the tooth using adhesive technology. The rationale behind its use is to help eliminate a potential area where plaque may accumulate in spite of good oral hygiene measures. Pit and fissure sealants can be recommended both for molars as well as premolars, the latter in the permanent dentition only. They have been found to be very effective in preventing decay.⁵⁷

The relation between diet and dental caries has also been established. The relation between carbohydrates and dental caries is well known. Several monosaccharides, disaccharides and polysaccharides have cariogenic potential. The factors that affect caries initiation and

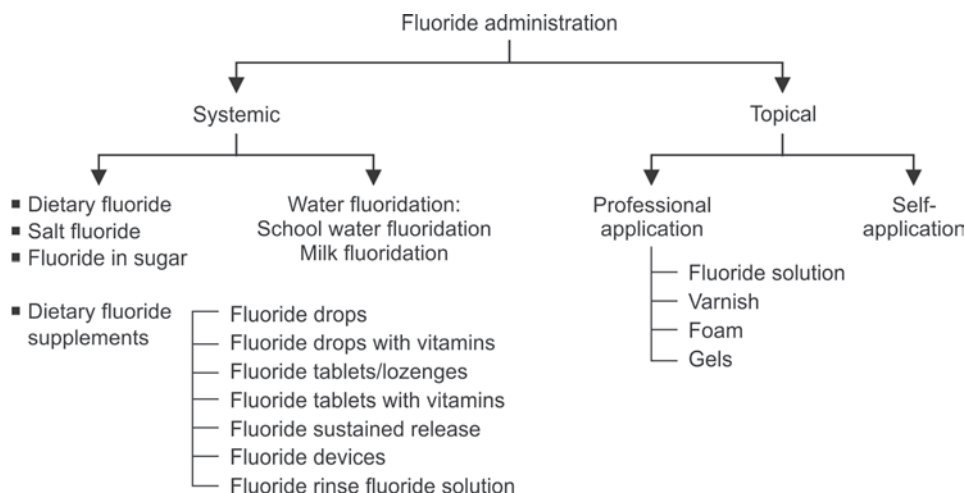

Fig. 6: Routes of fluoride administration

progression are, in some measure, related to the chemical form of the carbohydrate. For example, simpler carbohydrates, such as sucrose and lactose will have a higher cariogenic potential than a complex polysaccharide, such as cellulose which has no cariogenic potential. Further, the clearance rate of the carbohydrate from the mouth plays a very significant role. Sticky foods will have remain in the oral cavity for longer periods of time and thus have more cariogenicity. This is related to reduction in the pH of the mouth and plaque biofilm that promotes the growth and activity of acidogenic and aciduric microorganisms, which have the ability to metabolise these carbohydrates through extracellular enzymes.¹⁷ With sticky foods possessing cariogenic potential, the return of pH to normal following a sugar exposure is very slow. The frequency of the consumption of carbohydrate is also important. Thus strategies for dietary modification form an integral part in caries prevention and management. Oral hygiene measures would play an important role after a meal to aid in clearing away sugar from around the teeth thus restoring the pH in the mouth and reducing an acidic environment. Other potential measures could include changing the chemical nature of carbohydrate to make it less available for bacterial breakdown, such as the replacement of glucose (an aldose hexose) with sorbitol or xylitol. The provision of a terminal alcohol group instead of an aldehyde group helps resist acid formation by altering biochemical pathways and thus reducing dental caries. In another method, the addition of substances to a carbohydrate diet has been attempted to counteract products of bacterial metabolism. An example is the addition of phosphate groups to a carbohydrate containing diet which helps alter relative solubility of enamel and thus alters the caries rate.

Restorative Approach to Caries Management

Initial areas of demineralization can be managed through a minimally invasive approach that involves addressing dietary factors, improving oral hygiene measures, use of high fluoride content toothpastes (containing 2800 ppm or 5100 ppm fluoride), daily fluoride mouth rinses (0.05 percent sodium fluoride) and attempting re-mineralization using amorphous calcium phosphate-casein pyrophosphate combination (available as GC Tooth Mousse). However, if a definitive cavitation in tooth structure exists, then the line of management is the excavation of the decayed tooth structure and restoration of the remaining tooth with a suitable restorative material. This would help restore the tooth structure back to its original form, function and esthetic self. Several direct restorative materials are useful for this purpose and include glass ionomer cements and its variants, composite resins, amalgam, compomers, giomers and ormocers. An indirect restorative technique for the management of decay, known as the Hall technique for stainless steel preformed crowns has also been recommended with good success rate.

Pediatric Endodontics

If the carious process extends to involve the pulp of the tooth, then this is a definite indication for endodontic intervention, especially if the tooth is to be retained for a sufficiently long period in the mouth prior to its exfoliation and subsequent succession with a permanent tooth. Endodontics involves extirpation of the irreversibly inflamed or necrotic pulp, shaping and cleaning of the root canal system and then obturation of the same with a suitable filling material that is amenable to resorption (to facilitate exfoliation of the tooth). A more conservative procedure in endodontics would be a pulpotomy, wherein the pulp would be removed from the pulp chamber and amputated at the root canal orifices. This procedure would be undertaken only when it is reasonably certain that pulp within the root canals is not inflamed. Following the endodontic procedure, the badly broken down tooth could be protected with the help of a stainless steel crown in the case of molars and an adequate restoration of coronal tooth structure for the anterior teeth.

DENTAL TRAUMA

Dental trauma often results in a scenario that involves both general dentists and many dental specialists. Ideal treatment relies upon the expertise of a broad spectrum of dental specialists, such as oral surgeons, pediatric dentists, endodontists, orthodontists, prosthodontists and periodontists. Urgent care is frequently provided by the oral and maxillofacial surgeon or the pediatric dentist in a hospital accident and emergency department setting. Subsequently the patient may be referred to a general dentist or an endodontist for secondary level care, such as endodontic and restorative management. Later the orthodontist and prosthodontists and periodontist may become involved with additional treatment.

Incidence and Prevalence

Toddlers in the age group of 1.5 to 2.5 years are very susceptible to dental traumatic injuries. Maximum incidence of trauma is at the age of 4 years in the primary dentition and between 8 and 11 years for children in the permanent dentition. A sex distribution of boys to girls has been found to be in the ratio of 1:2.⁵⁸

Prevalence

Kessler has examined over 40,000 children over a period of 15 years and found the prevalence of anterior tooth trauma to be 4.6 percent. Andreasen in 1972 found a prevalence rate of 30 percent whereas Garcia Godoy (1990) reported very high figures of 72 percent. The prevalence of dental trauma in high school children ranged between 6 percent in an Australian study by Burton et al⁶¹ and 34 percent in an English study by Hamilton et al.⁶⁰ (Table 4). In the UK, a prevalence of 6 percent has been reported for

Table 4: Incidence of trauma in the anterior dentition

Country	Author	Incidence	Age group	Social group predominantly affected
Australia	Stockwell ⁵⁹	1.7 patients/100 children/year	6-12 years	Lower socioeconomic group
England	Hamilton et al ⁶⁰	4 patients/100 children/15 months	–	Higher socioeconomic group

8-year-old children and 17 percent for 12-year-old children in 1993.⁶² A study in Sweden observed a relatively high prevalence of traumatized teeth in children aged 7 to 15 years (30 percent) but this study also included traumatized primary teeth.⁶³ Gupta et al. examined 2100 school children between the age group of 8 and 14 years in a South Indian district and found prevalence rate of 13.8 percent.⁶⁴ A New Zealand study by Dearing observed a prevalence of traumatized incisors of 19 percent,⁶⁵ while a Swiss study revealed a prevalence of trauma to permanent teeth in children aged 6 to 18 years of 11 percent.⁶⁶ In South Africa, an overall trauma prevalence of 16 percent in primary school children was found.⁶⁷ The black population had a dental trauma prevalence of 13 percent and the white population a prevalence of 21 percent. An American study found prevalence of traumatized incisor teeth to be significantly higher among non-Caucasians compared with Caucasians, 17.5 percent and 21.7 percent respectively.⁶⁸

Etiology of Dental Traumatic Injuries in Children

Fall injuries seem to be a common cause of dental trauma. In the preschool age, these may be attributed to activities associated with learning to walk and stand. School age children suffer dental trauma often because of sports injuries, more so during their teens when they engage in contact sports. Children with malocclusions, especially proclined teeth are at an increased risk for injuring their maxillary anterior dentition. The late teens may be associated with automobile accidents. Another important cause of dental trauma is the battered child syndrome. It is extremely important for the attending clinician to be able to discern and recognize such an injury. Fights and physical violence, foreign bodies hitting the face and medical problems (like convulsive fits) are also likely causes for a traumatized dentition. The extent of injury itself may be determined by several factors, such as the energy of impact, resiliency and shape of the impacting object, direction of the impacting force and cushioning barriers that intervene between the impacting object and the teeth (such as the lip).

Classification of Dental Traumatic Injuries

Table 5 presents the classification of dental traumatic injuries from different authors. Figures 7 to 10 are some examples of dental traumatic injuries. Dental injuries can be quite disturbing for the child and the parent and usually need immediate attention from the dentist or other health care personnel available. Of all the different types

of injuries, an avulsion injury is one of the most dramatic and a cause for considerable distress. This injury is discussed in greater detail here as awareness regarding the appropriate on site management strategy and telephonic advice to the parent by the dentist/doctor is critical in determining the outcome and prognosis for the tooth that has been avulsed.

AVULSION

The term avulsion is implied for teeth which are completely displaced out of its socket (alveolus). It is alternatively referred to as *exarticulation*.

Cause

Any impact trauma can lead to avulsion. The main etiologic factors in the permanent dentition appear to be sports injury, automobile accidents and fights whereas in the primary dentition, falls against hard objects are a frequent cause.

Incidence

Reported incidence of tooth avulsion ranges from 1 to 16 percent of all traumatic injuries in the permanent dentition and from 7 to 13 percent of injuries to the primary dentition. The maxillary central incisors are the most frequently avulsed teeth in both deciduous and permanent dentitions. The most frequently involved age group is 7 to 11 years, with boys experiencing avulsion three times as often as girls. Single tooth avulsions are very common, but multiple avulsions are also occasionally encountered.

Examination

Thoroughly examine the patient irrespective of the fact of whether or not the tooth has been returned to the socket before coming to the dental office. Radiographs and clinical examination should be first directed at detecting possible alveolar fractures. If such fractures exist, prognosis is significantly reduced. The avulsed tooth itself should be examined for debris and contamination. One of the most important aspects is to learn the length of time of avulsion since the extra-alveolar time determines, to a large extent, the treatment modality undertaken as well as prognosis.

Biologic Considerations

When a tooth is avulsed, the attachment apparatus of the root, namely the periodontal ligament and cemental layer, are damaged. Concomitantly, the blood vessels at the apex

Table 5: Classification of dental traumatic injuries

Andreasen ⁶⁹	WHO Classification ⁷⁰	Garcia-Godoy ⁷¹	Ellis ⁷²
Crown infraction. Incomplete fracture of the enamel	Fracture of enamel of tooth	Enamel crack	Simple fracture of the crown, involving little or no dentine
Uncomplicated crown fracture. A fracture confined to the enamel or dentine but not exposing the pulp	Fracture of crown without pulpal involvement	Enamel fracture	Extensive fracture of the crown, involving considerable dentine, but not the dental pulp
Complicated crown fracture. A fracture involving enamel and dentine, and exposing the pulp.	Fracture of crown with pulpal involvement	Enamel-dentine fracture without pulp exposure	Extensive fracture of the crown, involving considerable dentine and exposing dental pulp
Uncomplicated crown-root fracture. A fracture involving enamel, dentine, cementum, not exposing the pulp	Fracture of root of tooth	Enamel-dentine fracture with pulp exposure	The traumatized tooth that becomes non-vital, with or without loss of crown structure
Complicated crown-root fracture. A fracture involving enamel, dentine and cementum, and exposing the pulp	Fracture of crown and root of tooth	Enamel-dentine-cementum fracture without pulp exposure	Total tooth loss
Root fracture. A fracture involving dentine, cementum, and the pulp	Fracture of tooth, unspecified	Enamel-dentine-cementum fracture with pulp exposure	Fracture of the root, with or without loss of crown structure
Concussion. Injury without abnormal loosening or displacement but with marked reaction to percussion	Luxation of tooth	Root fracture	Displacement of tooth, without fracture of crown or root
Subluxation (loosening). Injury with abnormal loosening but without displacement of the tooth	Intrusion or extrusion of tooth	Concussion	Fracture of the crown en masse and its replacement
Intrusive luxation (central dislocation)	Avulsion of tooth	Luxation	
Extrusive luxation (peripheral dislocation, partial avulsion)	Other injuries including laceration of oral soft tissues	Lateral displacement	
Lateral luxation		Intrusion	
Exarticulation (complete luxation)		Extrusion	
Comminution of alveolar socket		Avulsion	
Fractures of facial or lingual alveolar socket wall			
Fractures of alveolar process with and without involvement of the socket			
Fractures of the mandible or maxilla with and without involvement of the tooth socket			
Laceration of gingiva or oral mucosa			
Contusion of gingiva or oral mucosa			
Abrasion of gingiva or oral mucosa			

of the tooth are severed, thus rendering the pulp necrotic (Figure 11).

Treatment Objectives

Treatment is directed at avoiding or minimizing the damage to the attachment apparatus and combating pulpal necrosis. If the tooth has an open apex, then revitalization should be promoted whereas in the case of a closed apex,

potential toxins from the root canal should be eliminated by endodontic therapy.^{73,74}

Clinical Management

Management outside the dental office

The single most important factor in the success of management is the speed with which the tooth is replanted

Figs 7A to D: Luxation injuries. (A) Subluxation; (B) Extrusive luxation; (C) Lateral luxation; (D) Intrusive luxation

Fig. 10: Upper right central incisor with enamel and dentine crown fracture and extrusive luxation. The Upper left central incisor with lateral luxation (For color version see plate 19)

Fig. 8: Lip injury and crown fracture for the upper left central incisor exposing the pulp and with lateral luxation (For color version see plate 18)

Fig. 9: Same patient as in Figure 8 with a closer view (For color version see plate 18)

back in its socket. The prime focus in the immediate post-traumatic phase is prevention of drying of the tooth. Every effort should be made to replant the tooth within the first 15 to 20 minutes after exarticulation. If the dentist is notified by phone of a tooth avulsion, the following instructions must be relayed by the dentist/attending physician to the emergency room attendant, parent or any responsible adult who may be able to carry out the steps.⁷⁵

Figs 11A to C: An avulsed tooth: (A) Normal tooth; (B) PDL fibers stretch; (C) PDL fibers broken (PDL: Periodontal ligament)

- Hold the tooth by the crown (not by the root) and rinse gently (but not excessively) in running tap water (not icy) or saline.
- Do not scrub the tooth
- Gently replace the tooth in its socket, as close as possible to the original position as possible. Ask the patient to bite gently on a piece of cloth, gauze or handkerchief.
- Rush the patient to the dental office.

If doubt exists on the ability to replace the tooth in the socket adequately, the tooth should be stored quickly in an appropriate medium until the patient can get to the dental office for replantation.⁷⁶ Several options are available and are listed in order of preference as under:

- *Avulsed-tooth preserving system (Save-a-Tooth, Biologic Rescue Products, Conshohocken, PA):* This contains Hanks

Balanced Salt Solution (HBSS) and is a pH-preserving fluid and trauma reducing suspension apparatus with several advantages. It is composed of glucose, sodium chloride, potassium chloride, calcium chloride, magnesium chloride, sodium bicarbonate, sodium phosphate, magnesium sulfate. It possesses a pH of 7 and osmolarity ranging from 270 to 290 osm/liter. This system could be made available at schools, contact sport events in hospitals and emergency rooms. However, its high cost and non-availability in different parts of the world precludes its use.⁷⁷

- *Viaspan (Dupont Pharmaceuticals, Wilmington, USA):* This is a cold storage medium for organ transplantation possessing a pH of 7.4 and osmolarity of 320 osm/liter. This has proven to be a superior long-term storage medium preserving 76.7 percent vitality of periodontal ligament cells after 24 hours and 37.6 percent after 168 hours. It has also shown to reduce the incidence of root resorption. However, its high cost (\$300/liter) and short shelf life deter its widespread use.⁷⁷
- *Contact lens solution:* This solution is commonly available at many homes or easily purchased from a drug store. It does not preserve vitality as well as the previous two solutions, but is still extremely effective over short time durations. It consists of sodium chloride, a copolymer of polyoxyethylene and polyoxypropylene, sodium phosphate and preserved with polyhexamidine.⁷⁸
- *Milk:* This is considered the best storage medium for uncomplicated avulsion because it is usually readily available at or near an accident site, has a pH and osmolarity compatible to vital cells and is relatively free of bacteria. Milk effectively maintains the vitality of periodontal ligament cells for 3 hours, which usually allows adequate time for the patient to reach the dentist for replantation.^{74,77,78}
- *Keep tooth in mouth:* Placing the tooth in the buccal vestibule or under the tongue helps keeping it bathed in the saliva. The tooth is kept moist and at body temperature. But it is not an ideal method because of incompatibility of pH, osmolarity and the microbial loading in the oral cavity. Further, in the case of a young patient, or where the patient has lost consciousness, risk of accidental ingestion or aspiration is always high.^{14,74}
- *Keep tooth in physiologic saline solution*
- *Water*

Management in Dental Office

Emergency Visit

Recognizing that the dental injury might be secondary to a more serious injury is essential and, if need be, referral to an appropriate expert is recommended. The focus of the emergency visit is the attachment apparatus. The

aim is to replant the tooth with maximal number of viable periodontal cells on root surface that have the potential to regenerate and repair. Endodontics, on the other hand, is not initiated at the emergency visit and not extraorally, if any hope exists of vital periodontal fibers on the root surface.

A full history must be taken and encompass reconstructing the accident, site of injury, time of injury, dry time for tooth, storage medium for tooth and any other injuries sustained by the patient.

Local anesthesia is generally administered for conducting a thorough clinical examination. If the tooth is in situ and acceptably replanted at the site of avulsion, then determine whether it is in proper position and alignment with the adjacent teeth. The tooth should not be traumatized by occlusion. The mobility of the tooth should be noted and a radiograph taken. The vitality of the pulp must be assessed. If the replantation done at the accident site is unacceptable, then the tooth is gently removed and replanted after obstruction to correct placement is removed.

If the tooth was not replanted at all, then the replantation procedure is governed by the time since avulsion and the status of the root apex of the tooth (open or closed). Flow charts 1A and B represent the management protocol suggested by the American Academy of Paediatric Dentistry for the management of an avulsed tooth with an open or a closed apex.⁷⁹ In these cases, the socket should be left as unaltered as possible. Gentle irrigation to remove debris and light aspiration of blood clot is permissible. However, curetting the socket is definitely contraindicated.

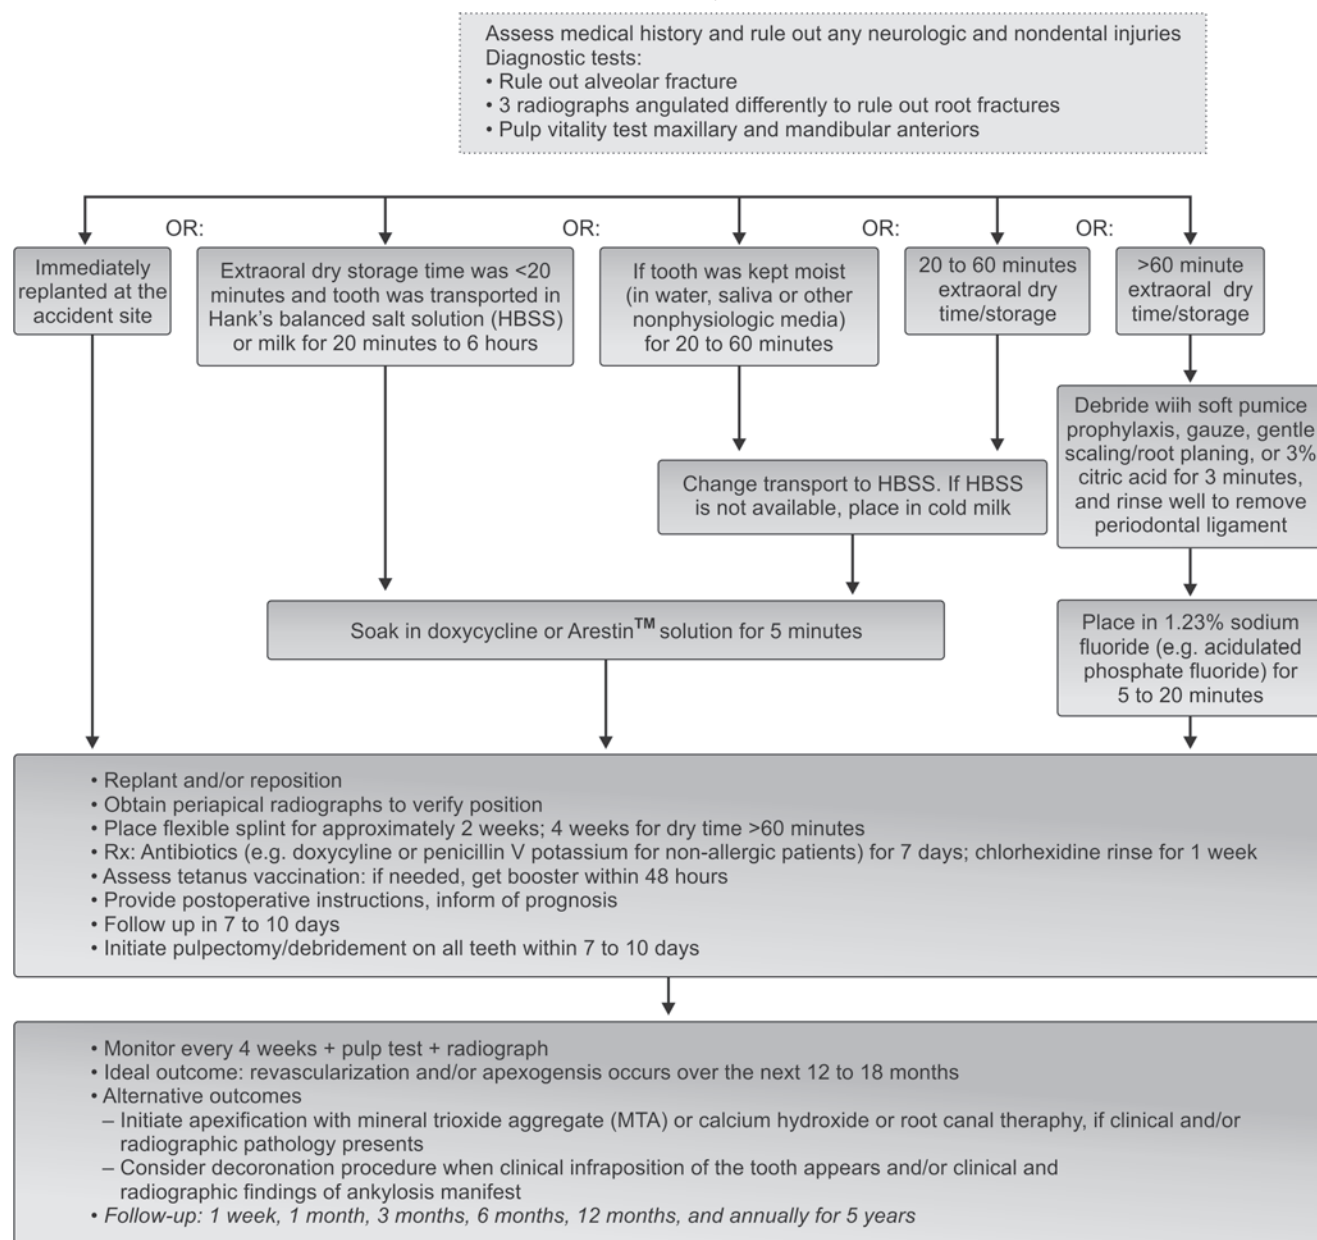

A semirigid physiologic splint should be placed for a period of 7 to 10 days.⁸⁰ Splinting affords stability to the tooth and allows physiologic movement of the tooth minimally during healing. It must also permit adequate maintenance of oral hygiene. The most commonly used splints are the acid-etch resin splint and the arch wire splint. When the splint is in place, the patient is asked to bite gently in a bite block (usually fabricated of softened wax) which forces the avulsed tooth as far into the socket as possible. If an alveolar fracture also exists, then the splint must remain in position for 4 to 8 weeks.

- Soft tissue management includes clearing the area of all dirt and debris and suturing all lacerations.
- Adjunctive therapy in the form of antibiotics and analgesics is recommended. Additionally, an antimicrobial mouthwash such as chlorhexidine gluconate is to be prescribed for a period of 7 to 10 days. The need for tetanus protection should also be evaluated.

Second Visit

This visit would include assessing the vitality of the tooth, removing the splint and deciding upon future options of whether to perform a root canal treatment. Subsequent

Flow chart 1A: Management an avulsed permanent incisor with an closed apex (Apex <1 mm)
(From American Academy of Paediatrics)

follow-up visits are mandated to monitor the status of the tooth.

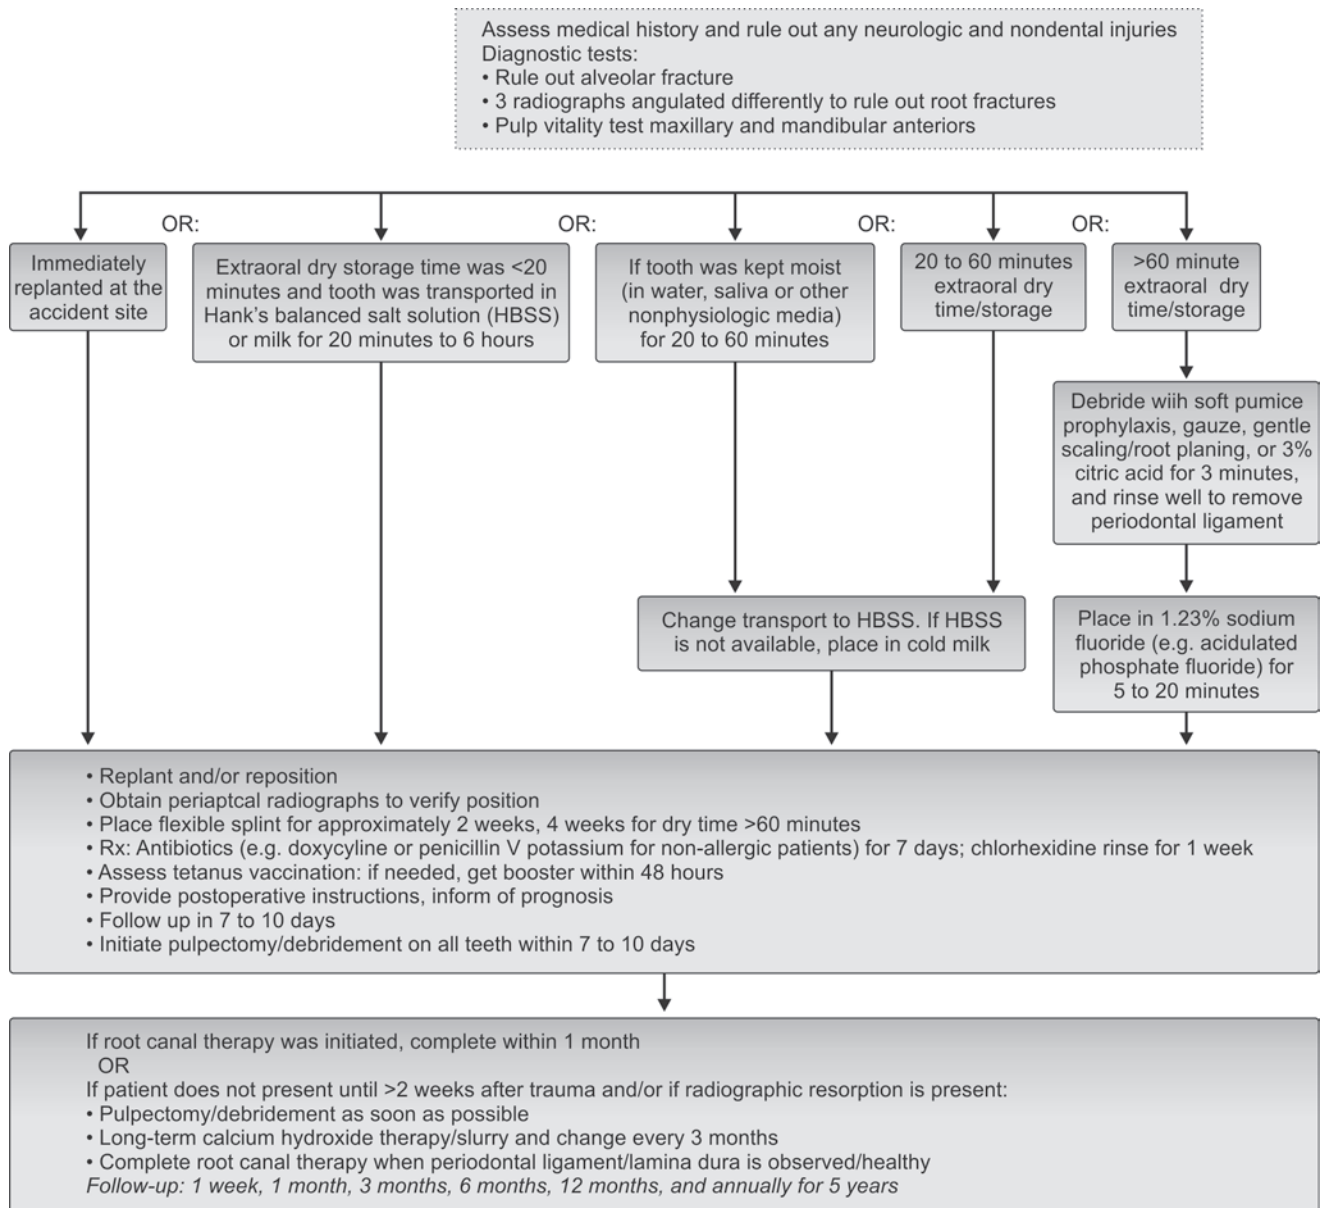

Prevention of Trauma in Children Engaging in Sports Activities

For children who participate in contact sporting activities, such as boxing, football and the like, it is always safer for the child to wear a protective mouth guard. The mouth guard serves to protect the teeth from impact trauma and distributes the force uniformly across the bony buttresses of the maxillofacial region rather than transmitting them on to the teeth. Mouth protectors are very useful in children predisposed to trauma, such as those with proclined

incisors and incompetent lips. The mouth guards could be either of the preformed or the custom made variety and can be worn by the child during the course of the activity only. Three different types of mouth protectors have been described:⁸¹

- *Stock protector:* These are made of latex rubber and are often used by boxers. They are not recommended for use by children as they are often poorly retained with the help of the opposing teeth. They also carry the risk of airway obstruction
- *Protector made in mouth:* These are again of two types:
 - A firm outer shell shaped as a dental arch which is filled with resin and placed in to the mouth. The

Flow chart 1B: Management an avulsed permanent incisor with an closed apex (Apex <1 mm)
(From American Academy of Paediatric Dentistry)

resin sets in the mouth but remains resilient at mouth temperature (Coe Dental Guard)

- A blank of polyvinyl acetate-polyethylene or polyvinyl chloride material which softens in water at about 75°C. Once softened, it is placed in the mouth and moulded with the tongue and fingers (Coe Redigaurd).

Both these variants can be accurately fitted in the mouth under the professional supervision of the dentist.

- *Professionally made protector:* These are the recommended mouth protectors because they are made on

an accurate model of the maxillary dentition. They are usually 3 to 6 mm thick. During heavy exercise, if the patient breaths through the mouth, the mouth will open while the mouth guard is still in place. However, there will be a gap between the guard and the lower dentition. Should there be a traumatic impact, the mandible will swing close and there is a risk for a base of the skull injury. Therefore, the mouth protector should be constructed so as to open the bite to a 'position of heavy breathing' to avoid this unfavourable consequence.

ORTHODONTIC TREATMENT

Orthodontics is that branch of dentistry concerned with prevention, interception and correction of malocclusion and other abnormalities of the dentofacial region. The word orthodontics is derived from the Greek words *orthos* meaning correct and *odontos* meaning teeth. The term “orthodontics” was first coined by le Felon.

In 1922, the British Society for the Study of Orthodontics defined the specialty as one that includes the study of the growth and development of the jaws and face particularly, and the body generally as influencing the position of the teeth; the study of action and reaction of internal and external influences on the development and the prevention and correction of arrested and perverted development.⁸²

Man has recognized the presence of dentofacial deformities and the need for its treatment centuries back. Crude appliances that were seemingly designed to regulate the teeth have been excavated by archeologists from around the world including Egypt, Greece, and Mexico.

Normal alignment of teeth not only contributes to the oral health but also goes a long way in the overall well-being and personality of an individual. Correct tooth position is an important factor for aesthetics, function and for overall preservation or restoration of dental health. The prevalence of malocclusion in the United States is estimated to be 35 to 95 percent of the population. Moderate to severe treatment need has been estimated to be at 30 to 40 percent of the population (NHANES III data).⁸³ While most malocclusions may not adversely affect the health of an individual, they nevertheless are capable of producing undesirable functional and esthetic imbalances. The following are some of the unfavorable sequel of malocclusion^{82,83} (Figs 12 and 13).

Poor Facial Appearance

Malocclusion is capable of adversely affecting the facial appearance of an individual.

Risk of Caries

Malalignment of teeth makes oral hygiene maintenance a difficult task, thereby increasing the risk of caries.

Predisposition to Periodontal Diseases

Malocclusion associated with poor oral hygiene is a frequent cause of periodontal diseases. In addition, teeth that are placed in abnormal positions can be a cause for traumatic occlusion with resultant periodontal tissue damage.

Psychological Disturbances

Malocclusion that adversely affects the appearance of person leads to psychological disturbances. Unsightly appearance of teeth makes a person highly self-conscious and turns him into an introvert. Thus treatment of malocclusion in such patients helps in improving the mental wellbeing and confidence.

Risk of Trauma

Teeth that are severely proclined are at a high risk of injury especially during play or by an accidental fall.

Abnormalities of Function

Many malocclusions cause abnormality in the functioning of the stomatognathic system, such as improper chewing, deglutition, defects in speech, improper respiration and so on.

Fig. 12: Radiographic examination prior to orthodontic treatment

Fig. 13: Patient undergoing orthodontic treatment with a fixed appliance (For color version see plate 19)

Temporomandibular Joint Problems

Malocclusion associated with occlusal prematurities and deep bite are believed to be a cause of TMJ problems such as pain and dysfunction.

Aims and Objectives of Orthodontic Treatment

The aims and objectives of orthodontic treatment have been summarized by Jackson as the Jackson's triad. The three main objectives of orthodontic treatment are:³¹

- Functional efficiency
- Structural balance
- Aesthetic harmony.

Functional Efficiency

Many malocclusions affect normal functioning of the stomatognathic system. The orthodontic treatment should thus aim at improving the functioning of the orofacial apparatus.

Structural Balance

The orofacial region consists of the dentoalveolar system, the skeletal tissue and the soft tissue including musculature. Stable orthodontic treatment is best achieved by maintaining a balance between these three tissue systems.

Esthetic Harmony

By far the most common reason for seeking orthodontic care is to improve the appearance of the teeth and face. Many malocclusions are associated with unsightly appearance of teeth and can thus affect the individual's self-image, wellbeing and success in society. Thus the orthodontic treatment should aim at improving the aesthetics of the individual.

Scope of Orthodontic Treatment

Orthodontic treatment involves the three main tissue systems concerned in dentofacial development, namely the dentition, the skeleton and the facial and jaw musculature. Orthodontic treatment can bring about changes in the dentition, the skeletal system and the enveloping soft tissue.

Alteration in Tooth Position

Orthodontic treatment is made possible by the fact that teeth can be moved through the bone to ideal locations by applying appropriate force on them. Most malocclusions involving the dental system can be effectively treated by moving teeth so as to normalize the occlusion.

Alteration in Skeletal Pattern

Malocclusion may be associated with skeletal disharmony involving the jaw bones (i.e. maxilla and mandible).

Deviations from the normal can arise in size, position and relationship between these skeletal components. It is within the scope of an orthodontist to apply appropriate orthopedic forces that are capable of restraining, promoting or redirecting skeletal growth as to normalize the skeletal system. The orthodontist can bring about changes in all the three planes of space, i.e. sagittal, transverse and vertical.

Alteration in Soft Tissue Pattern

The soft tissues that envelop the dentition are greatly influenced by the placement of the dentition. It is possible to bring about favorable changes in the soft tissue pattern by orthodontic treatment.

Services Offered by an Orthodontist

As most children are often seen by a paediatrician first, the early recognition of a malocclusion can fall into their purview.⁸³ Appropriate referral to a general dental practitioner or an orthodontist can then be made. The services offered by an orthodontist can be broadly classified as:

- Preventive orthodontics
- Interceptive orthodontics
- Corrective orthodontics
- Surgical orthodontics.

Preventive Orthodontics

Preventive orthodontics is that part of orthodontic practice which is concerned with the patient's and parents' education, supervision of the growth and development of the dentition and the craniofacial structures, the diagnostic procedures undertaken to predict the appearance of malocclusion and the treatment procedures instituted to prevent the onset of malocclusion.

Preventive orthodontics is a long range approach and it is largely a responsibility of the general dentist. Many of the procedures are common in preventive and interceptive orthodontics but the timings are different. Preventive procedures are undertaken in anticipation of development of a problem. Interceptive procedures are undertaken when the problem has already manifested, e.g. extraction of supernumerary teeth before they cause displacement of other teeth is a preventive procedure, while their extraction after the signs of malocclusion have appeared is an interceptive procedure.

The following are some of the procedures undertaken in preventive orthodontics:^{82,84}

- Parent education
- Caries control
- Care of deciduous dentition
- Management of ankylosed tooth
- Maintenance of quadrant wise tooth shedding timetable
- Check-up for oral habits and habit breaking appliance if necessary

- Occlusal equilibration, if there are any occlusal prematurities
- Prevention of damage to occlusion, e.g. from Milwaukee braces
- Extraction of supernumerary teeth
- Space maintenance for permanent dentition after the extraction/premature exfoliation of the deciduous dentition
- Management of deeply locked first permanent molar
- Management of abnormal frenal attachments.

Interceptive Orthodontics

Interceptive orthodontics includes procedures that are undertaken at an early stage of a malocclusion to eliminate or reduce the severity of the same. By undertaking appropriate interceptive procedures, it is possible to prevent establishment of a full-fledged malocclusion that may require long-term orthodontic treatment at a later age.

The procedure undertaken in interceptive orthodontics include:^{82,85,86}

- Serial extraction of the primary teeth in a planned, predetermined sequence at an appropriate age so as to guide the permanent teeth into correct positions
- Correction of developing crossbite
- Control of abnormal habits
- Space regaining
- Muscle exercises
- Interception of skeletal malrelation by the use of headgears and myofunctional appliances
- Removal of soft tissue or bony barrier to enable eruption of teeth.

Corrective Orthodontics

Orthodontic procedures undertaken to correct a fully established malocclusion. This entails therapy with fixed appliances, which may extend over a period of two to three years.

Surgical Orthodontics

They are surgical procedures that are undertaken in conjunction with or as an adjunct to orthodontic treatment. The surgical orthodontic procedures are usually carried out to remove an etiologic factor or to treat very severe dentofacial skeletal deformities that cannot be treated by orthodontic therapy alone.

MANAGEMENT OF THE ANXIOUS CHILD PATIENT

Dental anxiety is a common problem all over the world, and it not only prevents many patients from seeking care but it also causes stress to the dentists undertaking dental treatment. Dental anxiety should be seen as a multifactorial problem, and must also be seen as a continuum with

fear it is almost impossible to separate the two in much of the research undertaken in the field of dentistry, where the two words have often been used interchangeably. Fear is an unpleasant feeling that arises as a normal response to realistic danger. Anxiety is an emotion similar to fear, but arising without any objective source of danger. Phobia is a fear of a situation that is out of proportion to its danger, can neither be explained nor reasoned out and is largely beyond voluntary control and leads to the avoidance of the feared situation. The identification of these conditions will lead to the appropriate management for the child.

Fear is one of the primary emotions acquired soon after birth. Infant may be unaware of the stimulus causing fear, but as the child grows up, he is able to rationalize each stimulus and identify the ones which produce fear. Fear in children is generally classified as being either objective or subjective. Objective fears are those which are produced by direct physical stimulation of the sensor organs and are generally not of parental origin. These fears are felt, seen, heard, smelt or tasted. A child who has had an unpleasant experience at the dental office tends to acquire objective fears and thus not come back on their own volition. Subjective fears, on the other hand, are based on feelings and attitudes that have been suggested to the child by others without the child having had the experience personally. Such fears may be acquired from parents, friends, books, television and the like. For example, a mother's fear before a dental appointment may get transmitted to the child. These fears are more intense and disproportionate as compared with objective fears. Research in this area suggests that the extent of anxiety a person experiences does not relate directly to dental knowledge, but is an amalgamation of personal experiences, family concerns, disease levels, and general personality traits. Such a complex situation means that it is no easy task to measure dental anxiety and pinpoint etiological agents.

Measures to Overcome Fear

- Educating parents is extremely important prior to the dental visit so that they can prepare the child for dental treatment
- Fears should be given proper direction and control by parents. The child needs to be channeled to believe that there is no danger in dental treatment and that this is not a threat or a punishment
- The dentist needs to allow the child to develop a sense of attachment to him. This helps develop an environment of trust
- Parents should inform the child of what to expect in the dental office. Negative aspects and experiences should not be related to the child
- Parents need to be informed of the possibility of parental anxiety being transmitted to the child either directly or indirectly

- Parents need to be made aware of the modification of fear response in a child with age
- Children may develop a positive attitude by seeing pictures or videos of a dentist treating a smiling or a laughing child
- The waiting room should be decorated with posters, children's books, cartoons and videos playing children's entertainment programs
- For a preschool child, the mother should accompany the child to the surgery, not project her feelings on to the child and be encouraging and smiling
- Between ages 4 and 6 years, a child may begin to fantasize. This can be used to help overcome a fearful situation. For example, a playful situation could be conjured at home where the child simulates visiting the dentist, imagines himself sitting on a dental chair and have his teeth examined
- At school age, child begins to learn to manage fears by suggestion and imagination
- Around 7 years of age, the child is open to reasoning and explanation of treatment by the dentist
- At around 8 to 14 years of age, the child develops considerable emotional control and should not be bullied or laughed at
- In their teeth, children can be made to comply with dental treatment by informing them that the treatment would make them look better and smarter.
- d. Timid behavior/shy: usually due to overprotective parents. Due to anxiety, may prevent the child from listening attentively to the dentist.
- e. Whining type: A complaining type of behavior and the child complains of pain even for a painless procedure. He may allow treatment but may be crying through the procedure.
- e. Stoic behavior: Generally cooperative, sits, quietly, passively and accepts all dental treatment. This behavior may be seen in physically abused children.
- Lampshire (1970)
 - Cooperative: Physically and emotionally relaxed and cooperative through the procedure
 - Tense cooperative: Child is tense and cooperative at the same time
 - Outwardly apprehensive: Avoids treatment, usually child hides behind mother, avoids looking or talking to the dentist.
 - Fearful: Requires considerable support to help overcome the fears of dental treatment.
 - Stubborn/defiant: Passively resist treatment by using techniques to avoid accepting treatments that have been successful with them in the past.
 - Hypermotive: Children who are acutely agitated and resort to screaming, kicking and crying.
 - Handicapped: Children with special needs.
- Wilson's Classification (1933)
 - Normal or bold: Child is brave enough to face new situations, is cooperative and friendly with the dentist.
 - Tasteful or timid: Child is shy, but doesn't interfere with the dental procedures and is generally cooperative.
 - Hysterical or rebellious: Child is influenced by home environment, shows temper tantrums and is rebellious.
 - Nervous or fearful: Child is tense and anxious and fears dentistry.

Types of Behavior Encountered in Clinics

- Classification by Wright (1975)
 - Cooperative behavior: Relaxed and minimally apprehensive child
 - Can be treated with a straight forward behavior shaping approach
 - Lacking cooperative ability: very young child (0-3 years) or a child with special needs
 - Potentially cooperative: These children have the ability to cooperate but are unable to do so because of objective/subjective fears. Age varies from 3 to 13 years
 - Negative uncooperative:
 - a. Uncontrolled or Hysterical or Incurable: usually seen in preschool children (3-5 years). Temper tantrums characterized by pushing/ pulling legs and arms, crying and refusing to cooperate
 - b. Defiant behavior: seen in children of any age group. A stubborn child may throw temper tantrums. The children can be made to cooperate but firm guidelines need to be set.
 - c. Tense cooperative: Borderline behavior between positive and negative. The child is cooperative, does not resist treatment but is tense at mind. He may accept treatment but cry at an anxious moment.

Helping Anxious Patients to Copy with Dental Care

- Establish an effective preventive programme
- Establish good dentist-patient relationship
- Ensure treatment is pain-free
- Manage time effectively.

BEHAVIOR MANAGEMENT STRATEGIES

Nonpharmacologic Techniques

Communication

This is most important for the effective management of the child. A combination of both verbal and nonverbal communication techniques should be used. Verbal

communication is best for children over 3 years of age. The clinician's voice should be constant, gentle, express empathy and firmness at the same time. The content of the conversation should be such that the child feels that the dentist is his well-wisher. The child's name, age and general background should be known and the child should be addressed by his or her name and questions related to school, likes and dislikes can be asked to help make the child more comfortable in the operatory. Euphemisms can be used to explain dental terminology; the dental drill could be the whistling willy, the rubber dam a raincoat, dental caries could be addressed as the tooth bug, anaesthetic solution as the water to put teeth to sleep and a radiograph as a tooth picture. Non-verbal communication is via body language, smiling, eye contact, expression of feeling while speaking and showing concern.

Tell-show-do

The majority of young children have very little idea of what dental treatment involves and this will raise anxiety levels. Most children will cope if given friendly reassurance from the dentist, but some patients will need a more structured programme. One such structured method is the tell-show-do technique. As its name implies it centers on three phases:

- *Tell*: explanation of procedures at the right age/educational level
- *Show*: demonstrate the procedure and explain the purpose of each instrument to the child
- *Do*: follow on to undertake the task, praise being an essential part of the exercise.

This method is used in a graded fashion, starting from the least fear inducing object or procedure and moving on to more fearful objects. This method can be used in the first visit for the child (if old enough to comprehend, usually more than 3 years of age) and in subsequent visits when new procedures are being introduced.

Desensitization

The desensitization technique helps to alleviate fears and anxiety in children and is a method to reduce maladaptive behavior. The method has three different stages to its implementation. In the first stage, the child patient is taught how to learn to relax. In the second stage, different fear producing stimuli are identified starting from the least fear producing in an increasing grade to the most fear producing in relation to the child's principal fear and in the third phase these stimuli are introduced to the child in a similar fashion. The clinician must be cautious while introducing these stimuli; the child must first learn to relax before that fear stimulus is introduced. If the stimulus has been introduced before the child learns to relax, then the repeated introduction of the stimulus will further heighten the child's fear. At each stage and stimulus, the

tell-show-do technique must also be applied. It is important to first identify the principal fear producing stimulus such as the drill, the needle and the like. Then a hierarchy of stimuli related to this principal fear can be constructed. To illustrate an example for desensitization: if a child is fearful of the dental clinical environment, then the graded stimuli may be bringing the child to the reception room of the dental office which would have been decorated in a child friendly manner (Fig. 14), in the next phase, meeting the dentist and the dental nurse, then being taken across to the dental surgery, being made to sit in the dental chair and finally having a dental examination. If the child is fearful of a procedure, such as a filling involving the drill, then in a graded fashion, the child may be first exposed to a prophylaxis cup being moved over the child's teeth with the hand, then polishing teeth with the prophylaxis cup, introducing a fine diamond in a slow speed hand piece in to the mouth but not touching the teeth, the same procedure in the next stage but this time touching the tooth and in the final phase attempting caries excavation with a hand piece. The procedure is more difficult with needle desensitization.

Positive Reinforcement

Reinforcement has been defined as the strengthening of a pattern of behavior, which increases the probability of that behavior being displayed in the future. Approval from the dental team for good behavior will seem to reinforce the pattern of behavior and such behavior will then become the norm for the child in that particular situation. Usually good behavior will carry rewards that will help reinforce that behavior pattern. Such rewards can be by using appreciating keywords such as 'well done, terrific', 'very good' and the like. It is important to use these frequently and supplement them with encouraging body

Fig. 14: Oral hygiene instruction for a group of children in a child friendly non-threatening environment as a method of desensitization (*For color version see plate 19*)

language and a smile. At the end of the treatment session, good behavior should be commended again. Some form of reward, such as a cartoon sticker will also tend to help reinforce the cooperation in subsequent visits. It is important to avoid any reinforcement of poor behavior. If a child is uncooperative and treatment cannot be completed, and the child is allowed to return to the parent, a negative behavior pattern has been established. In such circumstances, it is best to continue and do some small task such as the placement of a temporary filling and then inform the child that the treatment session has finished for that day. The dentist should not display any form of anger. Disapproval methods for negative behavior are limited and may include expressing disappointment or not giving the child the reward (and informing them that the reward is being withheld).

Modeling

This makes use of the fact that individuals learn much about their environment from observing the consequences of other people's behavior. The procedure involves allowing the child patient to observe one or more individuals (models) who demonstrate appropriate behavior in a particular situation (for example while receiving dental treatment). Live models can include the child's siblings, parents or other child patients (Fig. 15). Other methods of modeling include posters, filmed models and other audiovisual aids. Learning through modeling is only effective when the observer is in a state of arousal, meaning that they are attentive and capable of receiving the information. It also helps if the model has more status and prestige as compared to the child so that the child feels like imitating the models behavior. It also helps if the child is able to recognize the positive outcome achieved from the behavior of the model. This technique is especially useful for children who have not had any previous dental experience.

Distraction

This technique attempts to shift attention from the dental setting towards some other kind of situation. Distracters such as videotaped cartoons, stories and music have been used to help children cope with dental treatment.

Coping

This is a mechanism by which the child is able to accept dental treatment. It has been defined as the cognitive and behavioral efforts made by an individual to master, tolerate or reduce stressful situations. The child patient under stress may prefer to draw support, comfort and reassurance from an authority figure in the dental office, this may be a dentist or a nurse. Coping has been considered to be either behavioral or cognitive in nature. Behavioral coping are physical and verbal activities in which the child

Fig. 15: Modeling (For color version see plate 19)

would engage to overcome the stressful situation. In cognitive coping strategies, the child may remain silent but is mentally undergoing thought processes that he has been trained with to make him feel calmer.

Voice Control

This technique utilizes the modification of the intensity and pitch of one's own voice in an attempt to dominate the interaction between the dentist and the child. Sometimes, this has been used alone and in other instances in combination with methods such as the Hand over mouth Exercise. Change in the tone of voice from gentle to firm is effective in gaining the child's attention and reminding him that the dentist is the authority figure and has to be obeyed.

Hypnosis

Hypnosis is an altered state of consciousness characterized by heightened susceptibility to produce desirable behavioral and physiologic changes. When used in dentistry, it has often been termed hypnodontia or psychosomatic suggestion therapy.

Aversive Conditioning

A child who displays a negative behavior and does not respond to moderate behavior modification techniques falls in to the category of Frankel's definitive negative behavior. Aversive conditioning can be a safe and effective method of managing extremely difficult behavioral problems. Under this category, the hand over mouth exercise (HOME) is one of the common techniques used. It was introduced by Dr Evangeline Jordan in 1920 with the purpose to gain the attention of the child so that communication can be achieved. Its use is indicated for a healthy child who can understand but exhibits defiance and hysterical behavior during treatment. It was recommended for use

for children aged between 3 and 6 years. It is important for the child to be able to understand simple verbal commands. It is not meant for use in children under 3 years of age, in handicapped and frightened children or children with special needs. Seeking consent before using this procedure is important. The technique involves placing the operator's hand over the child's mouth to completely stop the verbal outburst until the child shows willingness to cooperate. At this stage the hand is removed from the child's mouth and the child is complimented for good behavior. In this method, the child's airway is not restricted and the total duration of HOME is 20 to 30 seconds. Several variations of HOME have also been proposed such as hand over mouth and nose, airway restricted, towel over mouth, dry or wet towels over nose and mouth.

Physical restraints are a last resort for handling the uncooperative child in the nonpharmacologic techniques. Restraints may be required for children who are hypermotive, stubborn and defiant. The physical restraints have been classified as being either active or passive and are meant to restrict movement for the head, hands or feet and body of the child. The active restraints involve the child being actively held in the chair or parents lap to prevent any movement. A passive restraint is usually a commercially available product. For the body, restraints include the Pediwrap, Papoose board, sheets and bean bags with straps; for extremities, examples are Velcro straps and Posey straps. For the head, a head positioner or a forearm body support may be used. Mouth props are useful at the time of local anesthesia to prevent the child from closing his mouth. These have also been of help in young children who feel fatigued and the mouth prop helps keep the mouth open for a long appointment. Of late, many aversive techniques have fallen out of favor for use in the clinical environment and the use of pharmacologic techniques has been employed for the difficult child patient.

Pharmacologic Techniques

Sedation

Conscious sedation techniques have been employed for the management of the anxious child. Conscious sedation has been defined as a minimally depressed level of consciousness that retains the patient's ability to maintain a patent airway independently and continuously and to respond appropriately to physical stimulation and/or verbal command. The sedated child patient is therefore conscious throughout the procedure and in command of all normal protective reflexes. There are several routes for administering sedation to the patient and include the inhalation route, oral, intramuscular, intravenous and rectal routes. In the United Kingdom, inhalation route is a

common technique for sedating the child patient; others are rarely used. The inhalation sedation technique was pioneered, named relative analgesia. It is divided in to 2 stages: an initial stage of relative analgesia and then total analgesia. The drugs used in this technique are a mixture of oxygen and nitrous oxide as gases. Three planes of analgesia have been described depending upon the concentration of nitrous oxide used. Plane 1 produces moderate sedation and analgesia at levels of 5 to 25 percent nitrous oxide. At concentrations of 20 to 55 percent nitrous oxide, Plane 2 is achieved which includes dissociation sedation and analgesia. Plane 3 is acquired at 5 to 70 percent nitrous oxide which is known as total analgesia. Even though some analgesic effect is accrued from the procedure, the use of local anesthetic is still required, but the patient is more open to the suggestion of having this performed once he has been sedated. Specially designed continuous-flow machines are required for the methods and they have several safety features built in to them. Two commonly used machines in the UK are the Quantiflex RA and the MDM machines. In this procedure, a nasal mask is placed over the patient's nose and this is attached to tubing with oxygen and nitrous oxide inlets and outlets. At the start of treatment, a 100 percent oxygen concentration is maintained and the patient is allowed to breathe for at least 2 minutes. During this time, the operator checks for any leaks around the patient's nasal mask and ensures that the bag attached to the relative analgesia machine is moving. The flow rate of the gas can also be adjusted to an optimum at this stage. Following this, nitrous oxide is incrementally introduced and the dose titrated to a level that the patient is comfortable to accept. The maximum nitrous oxide concentration that is possible for delivery is 70 percent. The patient may have different sensations as nitrous oxide is increased ranging from tingling in the extremities, have a warm sensation in the body, sense of detachment, feeling drowsy to euphoria similar to alcoholic intoxication. These sensations are usually, but not always regarded as being pleasant. The main advantage of this technique is rapid recovery and the patient can be discharged within 5 minutes of from the end of the procedure. Usually, no special instructions are required preoperatively. However, children with upper respiratory infections, pulmonary disease and nasal obstructions are not candidates for relative analgesia.

General Anesthesia

This is the last resort for the management of the extremely anxious child patient. It is frequently used when multiple treatment are to be performed on the uncooperative child. Several teeth may be extracted and restored as well as preventive treatment also provided in the same general anesthesia session (Fig. 16).

Fig. 16: Treatment under general anesthesia
(For color version see plate 19)

EXTRACTION

An ideal extraction is the painless removal of the whole tooth or root or the remaining portion of the tooth with minimal trauma to the investing tissues so that the wound heals uneventfully and no future problems are created. For the young child who requires the removal of a primary tooth, the dentist should recognize the proper sequence of all the procedures. The dentist prepares the child by using a sensitive approach through his selection of words that indicate to the child the nature of the procedure. Figure 17 shows an extraction of a lower right molar tooth.

Indications^{14,87}

- Teeth which are hopelessly carious and not restorable.
- When there is extensive decay, which has resulted in death of the pulp and decay reaches to the furcation area of the roots
- When the primary teeth interfere with the normal eruption and alignment of their permanent successors:
 - Improper resorption of root causing deflection of erupting tooth found mainly in lower anteriors
 - Irregular resorption of the roots of molars, one root being resorbed more slowly than the others
 - Retained primary teeth when a permanent tooth is present and in normal position to erupt
- When there is a sinus opening through the mucoperiosteal membrane overlying the root
- When radiograph shows the evidence of periapical pathosis of poor prognosis
- When the root is fractures as a result of trauma and root canal therapy will not yield successful outcome
- When rudimentary supernumerary teeth or mesiodens are found in radiograph preventing the eruption of permanent teeth or causing any malalignment.

Contraindications

- Acute infections like stomatitis, Vincent's infection and herpetic stomatitis should be eliminated before an extraction is done because if virulence or the number of the organisms is high, it could result in bacteremia/viremia in the host. Exception to this condition is acute dentoalveolar abscess with cellulites, which requires immediate extraction of the primary tooth or an endodontic infection
- Malignancy contraindicates extraction as trauma enhances the speed of growth and spread of tumors. On the other hands, extractions are strongly indicated if the jaws and associated areas are to receive radiation therapy for the same malignancies
- Blood dyscrasias
- Diabetes mellitus

Many of these contraindications are relative in nature and extractions can be performed with adequate care, precautions and premedication. There are two absolute contraindications of extractions:

- Hemangioma
- Arteriovenous fistulas

In patients with hemophilia, rubber band extractions were previously used. A rubber band is placed around the tooth and results in the necrosis of the attachment apparatus with the tooth slowly extruding out of the socket. Today, appropriate cover with desmopressin, tranexamic acid mouthwashes and factor concentrates may be used, depending on severity of disease and nature of procedure.

Preoperative Preparation of the Parent and the Child

Preparing the Parent

- Dentist must have parental consent before the procedure
- When there is a doubt whether a carious primary tooth can be restored, the possibility of its being removed should be discussed with the parent before the treatment begins³⁸
- The parent may be concerned about excessive post-operative bleeding or pain. Reassure the parent that such pain usually does not occur when primary teeth are removed.
- Instruct the parent not to discuss with the child what the dentist will do. Rather, let the dentist do it. The parent's choice of words can be poor and they can unintentionally make the child fearful.

Preparing the Child¹⁴

- The 8 to 10 years olds who need teeth removed should have a working through period. This age group better adjusts to the removal of teeth when they are told four to seven days in advance of the procedure. However,

the younger children should be told on the day of the appointment about the procedure

- Tray containing the armamentarium for the removal of the teeth should be kept behind the dental chair
- Never hold the needle in front of the child
- Before giving local anesthesia, explain to the child that a sensation of pinching or an ant biting may be felt.
- It is extremely important that the child realizes the difference between pressure and pain
- Explain the sensation of numbness so that the child is prepared for it
- When checking for efficacy of the local anesthetic, note the eye reaction of the child as the verbal response may not be reliable

Precautions while Extracting

- While extracting the primary teeth, care must be exerted not to place the beaks of the forceps high up on the roots. There is a great possibility of damaging or inadvertently removing the partially formed permanent tooth with the primary tooth. In such an event, the permanent developing tooth must be replaced and the soft tissues sutured over the alveolus to hold the tooth in position (Fig. 17).
- Currettes should not be used for removing granulo-mas following primary tooth extraction because of danger of injury to the permanent tooth.

Control of Hemorrhage in Children Following Extraction

- Pressure packing with a moist gauze sponge held over the operative site for half an hour is the best method. The child should be asked to hold the gauze in between the teeth for this time duration
- For persistent bleeding, gel foam dipped in thrombin can be utilized. Surgicel may also be used for the purpose

Postextraction Instructions for the Child

- Child is to hold gauze in the mouth over the extraction socket for half an hour. Subsequently, the gauze pack is removed and immediately disposed out of the child's sight. After it has been ensured that a blood clot has been formed, the child should be dismissed from the dental clinic
- Child is not instructed to bite their lips as it may lead to ulceration. This is important since the effect of the anesthesia would last for about an hour and the child may constantly bite the lip in an attempt to feel the presence of the lip
- Clear instructions not to spit out the saliva but to swallow it. Spitting may dislodge the blood clot and lead to dry socket formation
- All liquid intake is to be from a glass. Straws are an absolute contraindication following extraction as the

Fig. 17: Extraction in the lower right quadrant
(For color version see plate 19)

negative force generated during the process of sucking may again disturb the blood clot

- Vigorous mouth rinsing to be avoided

Postextraction Instructions for the Parent

- Reinforce all the instructions given to the child
- A light, soft diet is recommended comprising of cold food only. No hard food is to be given to the child during the first 24 hours after extraction. Icecream, porridge, juices and the like, which do not entail any chewing should be the foodstuffs of choice.
- Appropriate analgesics can be prescribed for a period of two days^{88,89}
- A bloody pillow may be seen on the next day. This is attributable to slight oozing of blood from the socket, which gets mixed with saliva. If this saliva finds its way on to the pillow, it gives the parent an impression that there has been tremendous bleeding from the socket overnight. Parent should be reassured that this is not a cause to worry and should thus be pre-warned of such an event
- Instructions to call the dental surgeon in case of any symptoms developing in the child.

Extraction of Natal and Neonatal Teeth

Teeth that appear in an infant right from birth have been termed natal teeth and those that appear within the first month of life are known as the neonatal teeth.^{90,91} The occurrence of natal and neonatal teeth is rare; the incidence varies from 1:1,000 to 1:30,000.^{90,91} The teeth most often affected are the mandibular primary incisors.⁹² The occurrence of such teeth has been especially associated with the Riga Fede syndrome, a condition caused by the natal or neonatal tooth rubbing the ventral surface of the tongue during feeding leading to ulceration.^{90,93,94} Natal

or neonatal molars have been identified in the posterior region and may be associated with systemic conditions or syndromes (e.g. Pfeiffer syndrome, histiocytosis X).^{2,95,96} Although many theories exist as to why the teeth erupt prematurely, currently no studies confirm a causal relationship with any of the proposed theories. The superficial position of the tooth germ associated with a hereditary factor seems to be the most accepted possibility.⁹¹ These teeth generally belong to the deciduous complement and are frequently found to be slightly mobile. If the tooth is not excessively mobile or causing feeding problems, it should be preserved and maintained in a healthy condition if at all possible. There are reports of breast feeding problem with such teeth.⁹⁷ Close monitoring is indicated to ensure that the tooth remains stable. If excessively mobile, it carries the risk of being aspirated by the child during feeding. Failure to diagnose and properly treat this can result in dehydration and inadequate nutrient intake for the infant.⁹³ Treatment should be conservative and focus on creating round, smooth incisal edges.⁹⁸ If conservative treatment does not correct the condition, extraction is the treatment of choice. An important consideration when deciding to extract a natal or neonatal tooth is the potential for hemorrhage. Extraction is contraindicated in newborns due to risk of hemorrhage. The lack of circulating thrombin in the initial period of life, it is imperative that an initial dose of vitamin K be administered to the child to promote the formation of clotting factors. Subsequently extraction of such teeth can be done.

ORAL HABITS

Oral habits may be part of normal development; a symptom with a deep rooted psychological basis or may be the result of abnormal facial growth. Some of these have also been linked with medical conditions or adverse outcomes, including associations between acute otitis media and early cessation of breast feeding.⁹⁹ Digit sucking, lip and nail biting, bruxism, mouth breathing, tongue thrusting, etc. may be considered as some of the common habits seen in children.¹⁴ These habits bring about harmful unbalanced pressures to bear upon the immature, highly malleable alveolar ridges, the potential changes in position of teeth, and occlusion, which may become decidedly abnormal, if these habits are continued for a long time. It is important for the paediatrician, general dentist and the paedodontist to institute an early program of interceptive orthodontics in order to achieve harmonious occlusion and esthetics.

Definitions

Dorland: Habit can be defined as a fixed or constant practice established by frequent repetition.

Buttersworth: Defined a habit as a frequent or constant practice or acquired tendency, which has been fixed by frequent repetition.

Mathewson: Oral habits are learned patterns of muscular contractions.

Classification

- Obsessive (Deep rooted)
 - Intentional
 - a. Digit sucking
 - b. Nail biting
 - c. Lip biting
 - Masochistic
 - a. Gingival stripping
- Non-obsessive (Easily learned and dropped)
 - Unintentional
 - a. Abnormal pillowing
 - b. Chin propping
 - Functional habits
 - a. Mouth breathing
 - b. Tongue thrusting
 - c. Bruxism.

Development of Habit

The newborn develops some instincts, which are composed of elementary reflexes. An instinct is one where the pattern and order are inherited, while in a habit the pattern and order are acquired, if constantly repeated during the lifetime of an individual. At the beginning the infant makes an effort by frequent learning and practice, later on the muscles start responding more readily.

Sucking Reflex

The process of sucking is a reflex occurring in the oral stage of development and is seen even at 29 weeks of intrauterine life and may disappear during normal growth between the ages of 1 and 3-1/2 years. It is the first coordinated muscular activity of the infant. It is important for meeting both psychological and nutritive needs during feeding and apart from seeking nutritional satisfaction they also experience pleasurable stimuli from lips, tongue and oral mucosa and learn to associate these with enjoyable sensations, such as closeness of a parent. Babies who are restricted from sucking due to a disease or other factors become restless and irritable. This deprivation may motivate the infant to suck the thumb or finger for additional gratification.

Sucking Habits/Thumb/Digit Sucking

It is thought that such sucking behavior arises from psychological needs, so that normally developed infants have an inherent biological drive for sucking. These habits are often without psychological abnormality, though thumb or pacifier sucking beyond preschool years may reflect some psychological disturbance.

Sucking habits have been classified as:

- Nutritive sucking habits, e.g. breast feeding, bottle feeding

- Non-nutritive sucking habits (NNS habits), e.g. thumb or finger sucking, pacifier sucking

Johnson: Classified NNS habits based on factors that influence the severity of the habit. (Table 6)

Thumb sucking is a habit of concern to specialists in various fields, such as psychiatrists, psychologists, pediatricians, pediatric dentists, orthodontists and speech therapists. Despite extensive research considerable controversy still exists regarding sucking habits.

Thumb sucking and finger sucking can more generally be termed as digit sucking.¹⁰⁰

Classification

- *Normal thumb sucking:* Considered normal during the first and second year of life and is usually seen to disappear as the child matures. It is not known to generate any malocclusion
- *Abnormal thumb sucking:* When thumb-sucking habit persists beyond the preschool period then it could be considered as an abnormal habit. If the habit is not controlled or treated during this stage, it may cause deleterious effects to the dentofacial structures.

This can again be divided into:

- *Psychological:* The habit may have a deep-rooted emotional factor
- *Habitual:* The habit does not have a psychological bearing however the child performs the act out of habit. The habit is a cause for concern due to its potential to cause malocclusion.

Table 6: Classification of NNS habits

Levels	Descriptions
Level I (+/-)	Boys or girls of any chronological age with a habit that occurs during sleep.
Level II (+/-)	Boys below age 8 with a habit that occurs at one setting during waking hours.
Level III (+/-)	Boys under age 8 years with a habit that occurs at multiple settings during waking hours.
Level IV (+/-)	Girls below age 8 or a boy over 8 years with a habit that occurs at one setting during waking hours.
Level V (+/-)	Girls under age 8 years or a boy over age 8 years with a habit that occurs across multiple settings during waking hours.
Level VI (+/-)	Girls over age 8 years with a habit during waking hours.

(+/-) designates willingness of the parents to participate in treatment.

Subtelny has graded thumb sucking into 4 types:

Type A: This type is seen in almost 50 percent of the children where a whole digit is placed inside the mouth with the pad of the thumb pressing over the palate while at the same time maxillary and mandibular anteriors contact is present.

Type B: This type is seen in almost 13 to 24 percent of the children wherein the thumb is placed into the oral cavity without touching the vault of the palate while at the same time maxillary and mandibular anteriors contact is maintained.

Type C: This type is seen in almost 18 percent of the children where the thumb is placed into the mouth just beyond the first joint and contacts the hard palate and only the maxillary incisors but there is no contact with the mandibular incisors

Type D: This type is seen in almost 6 percent of the children when very little portion of the thumb is placed into the mouth.

Theories

Various theories have been proposed by psychologists to explain non-nutritive digital sucking and include the classical Freudian theory, the learning theory, oral drive theory and theory proposed by Johnson and Larsen which is a combination of psychoanalytic and learning theories (Fig. 18).

Maintenance of the Habit

Most children would cease digit sucking early in their developmental process by the age of three to four years. But an acute increase in the child's level of stress or anxiety due to some underlying psychological or emotional disturbances can account for continuation of a digit sucking habit, with conversion of an empty habit into a meaningful stress reduction response.

Causative Factors¹⁴

Socioeconomic Status

Families with high socioeconomic status have ample sources for providing nutrition to the child and the mother can feed the baby frequently to satisfy the infant's hunger. However, mothers belonging to the low socioeconomic group are unable to provide the infant with sufficient breast milk and the infant thus suckles intensively for a long time to get the required nourishment thereby also exhausting the sucking urge. Thus children from higher socioeconomic families have been reported to have a higher incidence of thumb sucking.

Working Mother

The sucking habit is commonly observed to be present in children with working parents. Such children may be

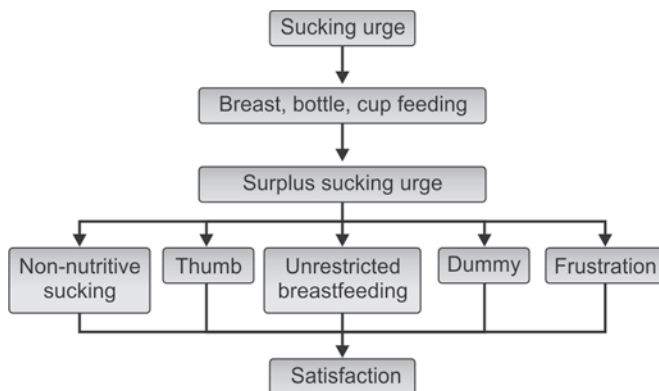

Fig. 18: Etiology of different sucking habits

taken care of by helpers/at nurseries and thus tend to develop some feeling of insecurity.

Number of Siblings

The development of the habit can be indirectly related to the number of siblings. As the number increases the attention meted out by the parents to the child gets divided. A neglected child may attempt to compensate his feelings of insecurity by the habit.

Order of Birth of the Child

It has been noticed that the later the siblings rank of a child, the greater the chance of having an oral habit.

Social Adjustment and Stress

Digit sucking has also been proposed as an emotion based behavior related to difficulty with social adjustment or with stress. The psychological effects may be compounded by the emotional impact of peer pressure and punitive and scolding parents.

Feeding Practices

Various controversies exist in this regard as to the influence of feeding modes to the development of the habit. Thumb sucking is seen to be more frequent among breast-fed children. Yet abrupt weaning from the bottle or breast has so been hypothesized to contribute to acquiring an oral habit.

Age of the child

The time of appearance of digit sucking habit has significance.

In the neonate: Insecurities are related to primitive demands as hunger.

During the first few weeks of life: Related to feeding problems.

During the eruption of the primary molar: It may be used as a teething device.

Still later: Children use the habit for the releases of emotional tensions with which they are unable to cope, taking refuge in regressing to an infantile behavior pattern.

In spite of contrasting views regarding the etiology there is some agreement that if the habit continues beyond the age of 6 to 7 months, it is difficult to break it until the child is 4 to 5 years. Thus it was suggested that the habit should be viewed by the clinician as a behavioral pattern of multivariate nature. Thumb sucking may begin for one reason and be sustained by other factors at different ages.

Diagnosis of Digital Habits

History

This should involve questions pertaining to feeding habits, parental care, work and occupation of mother, psychological evaluation and stress for the child, the nature of the habit, other habits concomitantly practiced by the child, the frequency, occurrence and duration of the habit.

Extraoral Examination

The digits

Digits that are involved in the habit will appear reddened, clean, chapped and with a short fingernail (a clean dish-pan thumb). Fibrous roughened callus may be present on the superior aspect of the finger and a deformation of the finger may be seen.

Lips

Upper lip may be short and hypotonic, passive or incompetent during swallowing and this leads to a further increase in the proclination of the upper anterior teeth.

Facial Appearance

A long narrow face with a narrow maxilla and a retruded mandible.⁹⁹

Other Features

Active thumb suckers also have a higher incidence of middle ear infections and frequently have enlarged tonsils accompanied by mouth breathing.⁹⁹

Intraoral Examination

Most studies have reported on the effects in the primary dentition and have used questionnaires to identify the habit type. Several dental anomalies that can be drawn from such studies include:

Maxillary anterior proclination and mandibular retroclination

Associations between dental arch abnormalities and digit sucking were reported as early as 1870s. When a child places a thumb between the teeth, it is usually placed at an angle so that it presses labially against the lower incisors and lingually against the upper incisors. This direct

pressure is responsible for the displacement of the incisors.^{101,102} This may lead to the development of a Class II Division I malocclusion.

Anterior open bite

This type of malocclusion arises due to a combination of factors:

- Interference with normal eruption of incisors due to an interposed thumb
- Excessive eruption of posterior teeth due to separation of the jaws, which alters the vertical equilibrium on the posterior teeth.⁹⁹

Constriction of maxillary arch

This may be because of the failure of the maxillary arch to develop in width due to an alteration in the balance between cheek and tongue pressures.⁹⁹

Posterior crossbite

It occurs as a consequence of constriction of the maxillary arch. The unbalanced muscle forces on the maxilla exerted by the cheek muscles are not met by the pressure from the lingual musculature, which is normally present.¹⁰³

Prevention

The etiology of thumb sucking focuses on a predominant psychological background. Its prevention should be directed toward the motive behind the habit. Parents when questioned may reveal that the child practices the habit when bored and left to himself, or it could be just before he goes to sleep. In such cases, the parents can be counseled on keeping the child engaged in various activities. When parents are at home, they should be advised to spend ample time with the child. At night, this can be reinforced by singing lullabies, playing soothing music or by narrating stories till the child sleeps. Care should be taken when feeding infants in that the duration of feeding should be adequate so as to enable the child to exhaust his sucking urge and feel completely satisfied.

Treatment Considerations

- *Psychological status of the child:* Diagnosis and management of any psychological problem should be planned before treatment of any potential or present dental problem.¹⁰⁴
- *Age factor:* If the child desists with the finger sucking habit within the first three years of life, the damage incurred, such as open bite, is temporary provided the child's occlusion is normal. No treatment is provided in this age group. If a malocclusion is caused by digit sucking and the habit is discontinued between the age of 4 and 5, self correction of the habit can be expected. When this continues after six years or into the mixed dentition phase, the malocclusion will not self-correct.

- *Motivation of the child to stop the habit:* This approach involves dealing directly with the child and explaining the problems associated with the habit. The first step, which would facilitate the treatment is to instill a desire in the child to stop.
- *Parental concern regarding the habit:* It is important that the child should not be embarrassed or criticized rather help should be offered to deal with this difficult habit. Negative reinforcements in the form of threats, nagging and ridicule would only entrench the habit.
- *Other factors:* Self-correction again depends on the severity of malocclusion, anatomic variation in the perioral soft tissue and the presence of other oral habits, such as tongue thrusting, mouth breathing and lip biting habits.

Treatment Plan

- Psychological therapy
- Reminder therapy
 - Extraoral approaches by employing hot tasting, bitter flavored preparations or distasteful agents applied to fingers or thumbs. For example, Cayenne pepper, quinine or asafetida. This is only effective if the habit is not firmly entrenched. A long sleeve gown has been also attempted which prevents the child putting the digit directly into the mouth and thus eliminating the pleasurable sensation from digit sucking.¹⁰⁵
 - Intraoral approaches include various orthodontic appliances employed to break or attenuate the habit. Removable appliances include palatal crib, rakes, palatal arch, lingual spurs and so on. Fixed appliances such as upper lingual tongue screens appear to be more effective in breaking these habits. If the child has made appreciable changes in his habit by 3 months, the appliances can be safely withdrawn.
- Mechanotherapy
 - Fixed intraoral antithumb sucking appliance
 - Blue grass appliance.¹⁰⁶

Haskell (1991) introduced this appliance, for children with a continued thumb sucking habit, which is affecting the mixed or permanent dentition. It consists of a modified six sided roller machined from Teflon to permit purchase of the tongue. This is slipped over a stainless steel wire soldered to molar orthodontic bands and placed intraorally for 3 to 6 months. Instructions are given to turn the roller instead of sucking the digit.

Mouth Breathing

This habit may develop due to nasal obstructions which may be transient, nasal congestion or sometimes during periods of exercise or activity. Some children are known

to be mouth breathers primarily because of chronic nasal congestion (asthma/allergy), enlarged adenoids or those with cleft deformities. The prevalence of this habit is hard to quantify. A study has reported it to be 40 percent for first-grade children when observed for 15 minutes.¹⁰⁷ Another study asked parents whether their children were regular mouth breathers and reported a prevalence of 9 percent at age 4 years. Mouth breathing can effect orofacial development as it affects the position of the tongue.⁹⁹ Mouth breathers also tend to have an open mouth posture. Because of these factors, the tongue is usually lower in the mouth rather than resting against the roof of the palate. Thus the maxillary arch is generally narrower in these children. The open-mouth posture for the mouth breathing children also leads to an over-eruption of the molars. This leads to a downward and posterior rotation of the mandible. This leads to an increase in face height and a retrusive mandible. It is desirable that an early correction of the respiratory problem be made so as to avoid the development of altered skeletal patterns of growth. Referral to an otolaryngologist should be undertaken to prevent complicated fixed orthodontic treatment at a later date.

Bruxism

Bruxism is the habitual grinding of teeth while the child is sleeping. Its incidence has been reported between 20 and 24 percent in children and it may be linked to stress and some parasomnias.^{108,109} Studies have suggested that this decreases with age, is largely self-limiting and rarely requires intervention.

CONCLUSION

The pediatrician is most often the first port of call for all parents whose child is unwell. This also includes dental problems. It is important for the physician to be able to recognize some of the maladies and make an appropriate onward referral to a dentist or dental specialist for required management. Advice in emergency situations to the parents may also be required and a closer understanding of dental disease and issues relating to dentistry will help improve health care provision for the child patient.

Industrialization and Globalization: Negative Aspects

Anupam Sachdeva, Vinita Jain

Environmentalism is a universally accepted concept, however, its actual meaning and its relationship to health outcomes is not always clear. In 1984, 2,000 people died of a hazardous chemical release accident in Bhopal, India. On March 24, 1989, 11 million gallons of North Slope crude oil poured into the unsullied waters of Prince William Sound when the Exxon Valdez struck a reef. Contingency plans created for dealing with such a spill failed after 12 years of trouble-free operations. The Prince William Sound has become a laboratory for scientific research in oil pollution of a pristine environment.¹

The Persian Gulf War resulted in massive environmental pollution. Oily clouds from burning wells rose as high as 20,000 feet. From the blackened burning landscape to the fine mist of oil particles suspended in the air, the Gulf suffered an environmental insult the human health effects of which are yet to be determined. The US military now struggles to understand the cause of an illness termed the “Gulf War Syndrome”.

In 1992, at Rio de Janeiro, the earth summit developed a comprehensive document termed Agenda 21 for planning in areas affecting relationships between the environment and the economy.² Agenda 21’s proposal to adopt precautionary approaches in managing the life cycle of toxic chemicals to prevent and reduce risk to human health and the environment involved four programs:

- Promote the prevention and minimization of hazardous waste
- Promote and strengthen institutional capacities in hazardous-waste management
- Promote and strengthen international cooperation in the management of trans-boundary movements of hazardous waste
- Prevent illegal traffic in hazardous waste.

Emergence of new diseases and old diseases can be traced to factors of social disruption, war, human behavior, lack of public health infrastructure, and environmental disruption (Table 1).³

Table 1: Impact of environment

<i>Categories</i>	<i>Examples</i>
Human behavior	Sexual behavior; drug use; travel; diet; outdoor recreation; use of child-care facilities
Environmental changes	Deforestation and reforestation; changes in water ecosystems; flood and drought; famine, global warming
Public health insurance	Curtailment or reduction in prevention programs; inadequate communicable disease surveillance; lack of trained personnel (epidemiologists, laboratory scientists, vector and rodent control specialists)
Microbiological adaptation and change	Changes in virulence and toxin production; development of drug resistance; microbes as cofactors in chronic disease
Societal events	Economic impoverishment; war or civil conflict; population growth and migration; urban decay.
Health care	New medical devices; organ or tissue transplantation; drugs causing immunosuppression; widespread use of antibiotics
Food production	Globalization of food supplies; changes in processing and packaging

Climate change is another potential public health challenge that can result in disease emergence. The global temperature has increased between 0.3°C and 0.6°C during last century and has been strongest at night in the Northern Hemisphere. A CO₂, a major “greenhouse” gas, arises from natural sources as well as human-related fuel combustion. Computer modeling predicts that, should the atmospheric CO₂ double over next 100 years, the global temperature would increase 1.5°C to 4.5°C (3°F to 9°F). Such a temperature change would cause the seas to rise 15 to 90 cm and alter the ecological pattern of infectious diseases such as malaria, yellow fever, encephalitis, cholera, and dengue fever.⁴

Another effort was made a few years later when the world body met at Vancouver.

THE VANCOUVER STATEMENT ON THE GLOBALIZATION AND INDUSTRIALIZATION OF AGRICULTURE—JUNE 1998

Five decades of the so-called Green Revolution have not only led to the destruction and contamination of water, soil, biodiversity, and human communities, but exacerbated hunger worldwide. One of the most critical impacts of industrial agriculture is climate change, which will destroy the natural basis of agriculture itself. The patenting of life, corporate ownership and manipulation of our genetic heritage is one of the greatest threats ever imposed by industrial agriculture: the human right to feed, clothe and shelter ourselves and our families is at stake.

Institutions and treaties such as the World Trade Organization, the General Agreement on Tariffs and Trade, Codex Alimentarius, North American Free Trade Agreement, the Food and Agriculture Organization, and the European Union have accelerated the process of agricultural industrialization and globalization while promoting the rights of corporations over those of people.

- Farmers around the world are farming in ways that respect their unique ecological and cultural communities. Building on their wisdom, all farms of the twenty-first century can be ecologically regenerative, community sustaining, biologically and culturally diverse, as well as energy conserving. We must not only build upon the existing knowledge and vision of farmers, but we must expand partnerships and create coalitions that serve to re-empower them.
- In order to rescue our food system, we need more skilled farmers who have access to land, seed, and the knowledge of local biological systems.
- A healthy food system needs clean land, air, water and soil and the right to save seeds to ensure future harvests.
- Scientific organizations and transnational corporations that are experimenting with, and releasing poisons, synthetic compounds and genetically modified

organisms into the biosphere should be held fully accountable for the safety of their practices and products.

- Corporations, scientists and governments should honor the precautionary principle and take preventive action in the face of scientific uncertainty in order to avoid cultural and ecological harm.
- They concluded that the consumers have a right to know where their food comes from, what is in it, and how it was produced. Furthermore, farmers and consumers have a right to maintain local control over food production, distribution and consumption.
- Our bodies, our plants and animals, our air, water, land, and soil, are not commodities and are not patentable. When a food production system violates the rights of citizens and the natural order of the planet's ecosystems, it is essential that we the people make use of our inalienable freedom to correct those who abuse.

SEMICONDUCTOR MANUFACTURING HAZARDS

Electronics is projected to be the world's largest industry in terms of revenue. Semiconductor integrated circuits, known as chips, underpin the entire electronics industry. This completed chip poses many health problems. Three broad areas of concern are:

- The clean room environment
- The manufacturing process and tools
- Selected chemicals used.

CLEAN ROOM ENVIRONMENT

In clean room workstation, air is always being pushed out towards the worker's breathing zone. Though this ventilation technique protects the product under the hood from any particles in the room, but can expose the worker to vapors of other air contaminants being generated in the workstation. As the bulk of air entering the clean room is re-circulated from the core areas, workers can be exposed to any contaminants released in the core area. Among these contaminants are gas leaks from uncontrolled lines or cylinders, oil mists from pumps and tools, vapors from wet chemical spills, and air from work aisles that communicate with the same core. Exhaust ventilation is provided to remove contaminated air. It is necessary to provide a fine balance between the laminar airflow and exhaust to prevent the product from being contaminated, as well as to prevent emissions from escaping from the front of the wet station towards the worker.⁵

CLEAN ROOM HEALTH PROBLEMS

Semiconductor clean rooms are hot, dry, and windy. Humidity is maintained constant from 15 to 50 percent to protect wafers from condensation of water droplets. This warm, relatively dry air moves constantly at 80 to 100

linear feet per minute. These three conditions, especially the rapid air movement, dehydrate the stratum corneum of the skin and the mucous membranes. "Low humidity occupational dermatosis" can manifest as pruritus, urticaria or eczema.

Upper Respiratory Problems

Complaints of mucous membrane, dryness of eyes, nose and throat are relatively common. Recurrent epistaxis, sinusitis, and laryngitis may occur in a small percentage of workers.

Eye Problems

The semi-desert conditions of the semiconductor clean room can also contribute to eye problems. Some workers complain of constantly irritated eyes, but usually this can be ameliorated by the use of over-the-counter eye drops to moisturize the conjunctivae.⁵

Multiple Chemical Sensitivities

A proposed and controversial syndrome termed multiple chemical sensitivities refers to the occurrence of diverse symptoms involving multiple organ systems (e.g. CNS, GIT, skin, respiratory tract) occur when the individual is exposed at very low levels to multiple chemically unrelated compounds.⁶

Mass Psychogenic Illness

Chemical odors are common in clean room settings. The combination of these odors with monotonous work, and the tendency to be isolated from management, makes a natural setting for mass psychogenic illness. Mass psychogenic illness (MPI) is not a clinical diagnosis; it is a sociologic phenomenon describing the collective behavior of a group of people. The words psychogenic illness implies that psychopathology is present in the affected individuals. Quite the opposite, the response although not conscious, is a natural health coping reaction to a stressful work situation perceived to be unresolvable.⁷

PLASTIC MANUFACTURING

Articles made from plastics are found in appliances, automobiles, toys, home furnishings, clothing, insulation, food and beverage containers, and countless other applications.

Health Hazards

Most of the polymerization processes take place in closed systems, and health hazards of resin manufacturing are similar to those of the petrochemical industry.⁸⁻¹¹ Various procedures in plastic manufacturing which may cause hazards may be broadly categorized as follows:

- Workers may have exposure to dust and vapors containing chemical intermediates, polymers, and additives

during loading, mixing, palletizing, and maintenance operations.

- Plastic processing equipment operates using high temperatures and pressures and needs to be equipped with proper guards and safety rails to avoid serious burns, amputations, and crush injuries.
- Finishing operations may expose workers to a variety of other chemical compounds, such as solvents and adhesives.
- Cutting of plastics may result in repetitive motion injuries, such as tendonitis, sprains, and carpal tunnel syndrome.

Combustion Product Hazards

Overheating of plastics results in thermal decomposition, as well as release of oligomers, monomers, and other combustion products. Although combustion hazards are primarily respiratory irritants (hydrochloric acid, aldehydes), significant pulmonary injury from nitrogen oxides and phosgene, as well as systemic poisoning from CO and cyanides, may occur.

Plastics are produced by polymerization of ethylene and propylene. And both ethylene and propylene are asphyxiant gases. Several of the organometallic catalysts used are potent respiratory and skin irritants. Occupational asthma has also been reported due to both the agents.⁸

High-density polyethylene is used to form containers ranging from fuel tanks to milk bottles. Low-density polyethylene has higher clarity and is used for films, coatings, shrink-wrap, and food packaging. Polypropylene is used in containers, including medical syringes, as well as automotive components.

Polyvinyl Chloride

Polyvinyl chloride (PVC) is made through polymerization of vinyl chloride monomer (VCM), which is a known human carcinogen, and is associated with tumors of the brain, liver, and the lung. In India, VCM is imported in a compressed and liquefied form and is very dangerous to transport as any leaks can lead to explosions. A chemical called tetrahydrofuran is used as a solvent in the polymerization of PVC. It may be inhaled or ingested causing irritation of the eyes, nose and respiratory tract, headache, dizziness, and potential damage to the central nervous system, liver, and kidneys.¹⁰

The PVC is used in upholstery fabrics (as PVC rexine), shoe soles, teethingers for babies, flexible toys like dolls, pipes or tubing's, medical disposables like blood or plasma transfusion bags, and more recently as venetian blinds and shower curtains.

Of all the plastics used in India, PVC has the biggest market share at 28 percent. Polyvinyl chloride is now trying to enter areas such as stationary, apart from providing

cabling, such as for the telecom industry. The PVC is the world's most toxic plastic, spreading sickness in each stage of its life-cycle.

Plasticizers are additives, which reside between the PVC molecules and give the plastics their flexibility. As they are not chemically bound, they have the tendency to migrate into foods wrapped in PVC plastic, carrying other components of the plastic such as stabilizers.

The PVC can be colored by mechanically dispersing solid pigment particles so that each is covered with binder molecules, without trapping air between binder and pigment. Since colorants are not polymerized with pigment, they too can migrate. The additives used commonly include phthalates, colorants containing lead and calcium, and stabilizers containing barium.

As PVC contains chlorine, on burning it releases a toxic acidic gas, as well as dioxins and other organochlorines. The incineration of a kilogram of PVC produces up to 50 g of dioxin (TEQ), which is enough to initiate cancer in 50,000 laboratory animals. The smoke also contains hydrogen chloride (HCl) and this combines with moisture (for example, in the lungs) to form hydrochloric acid, which causes serious burns. It is for this reason that in Delhi, many firemen suffered from acute respiratory distress after several hours of fighting the great PVC fire in 1995.

Toys and Teethers

For children exposure to PVC outside the womb begins with toys. Many flexible, chewable plastic toys are made of PVC. When children bite or chew them, they also take in phthalates, as they are not bonded well with plastics and easily leach out. The most commonly used phthalate, DEHP, is a possible human carcinogen. It may cause renal failure, hepatic toxicity, reproductive abnormalities, including testicular atrophy, subtle affects on sperm production, and cell line transformation.

A study of PVC toys in India showed that Indian toys were most phthalate rich. These included teether's, in which DEHP was found.

Furthermore, PVC flooring releases high concentrations of plasticizers and contributes to 'sick building syndrome', a condition commonly reported in modern office blocks, when persons inside the buildings begin to feel tired and ill. A child is particularly very susceptible to PVC flooring as they spend a lot of time on the floor, and close to the floor.

The PVC is also widely used in the medical sector. It makes the patient more ill as phthalates leak out of the tubing's into their bodies. Phthalates like DEHP migrate into fluids and have been detected in the blood found in blood banks. Dialysis patients who receive long-term and regular blood transfusions, their blood comes in contact with the PVC tubing of a dialysis machine, hence, predisposing them to high levels of DEHP per treatment.

Medical Surveillance

Medical surveillance in terms of annual examination of workers working on vinyl chloride, including liver enzymes and assessment of lung functions is recommended.¹²

Elevations of serum bile acids and hyaluronic acid have also been reported in workers. An elevation of von Willebrand factor has also been reported in individuals diagnosed with angiosarcoma,¹³ and levels have been used to track disease progression. Vinyl chloride induced mutations in *p53* and *k-ras* genes have been identified through identification of altered serum proteins, and these show promise in identifying excessive exposure as well as disease risk.¹⁴

Polystyrene

Polystyrene packaging materials are used widely for food products such as egg cartons, plates, cups, and disposable food containers. There is potential exposure to unreacted styrene monomer during resin production, particularly during mixing, loading, and maintenance operations.

At high concentrations, styrene is a respiratory and mucous membrane irritant. Skin contact may result in the development of primary irritant dermatitis. The manifestations of overexposure to styrene include lightheadedness, dizziness, and in-coordination. Limited clinical investigations of workers with long-term exposure to styrene have suggested subtle central and peripheral nervous system injury as well as possible liver damage.¹⁵ Styrene is mutagenic and has been associated with the induction of chromosomal aberrations in humans, although human epidemiologic studies have shown a definitive cancer risk.¹⁶

Various other plastics may cause dermal, respiratory, mutagenic, and carcinogenic problems. They are given in Table 2.

HEALTH HAZARDS OF RUBBER AND TYRE INDUSTRY

The environmental impact associated with the disposal of tyres is quite substantial and frequently overlooked because of the obvious importance of worker exposure issues. The most important human health and environmental problem surrounding the treatment, storage, and disposal of tyres are associated with their large-scale combustion hazard.

- Tyre fires are commonly associated with arson, although lightning strikes are also a recognized ignition source, as are spontaneous outbreaks that are caused by a combination of heat and vibration. Once ignited, tyres produce approximately 18,000 BTUs per second of heat energy, compared with approximately 6,000 BTUs per second for a traditional class 'A' fuel fire.²²

Table 2: Plastic resins and their impact

<i>Name of the compound</i>	<i>Source of exposure</i>	<i>Clinical features</i>	<i>Preventive measures</i>
1. Acrylic	Used in coatings, lights, windows, and face shields	Methacrylates are upper respiratory and mucous membrane irritants ¹⁷	Limit skin contact Patch testing confirms the diagnosis
2. Fluoropolymers and chloropolymers	Used in nonstick cookware, in forming sheaths and coatings for wires and cables	During processing fluorinated and chlorinated hydrocarbons are employed. Overexposure may cause solvent narcosis ¹⁸ Polymer fume fever may occur due to thermal decomposition	Local exhaust ventilation to limit exposure to thermal decomposition products Prevent polymer fume fever by good housekeeping and restricting smoking
3. Phenolic resins	Used in production of building materials, such as plywood and adhesives. Resoles are used in electrical components and in laminating. Phenolic resins are used to coat fabrics imparting crease resistance	Contact dermatitis may result from the handling of raw materials. Dust produced may cause pulmonary impairment and X-ray changes consistent with pneumoconiosis	Avoid skin contact Proper respiratory protection should be worn while handling resin powders
4. Polyurethanes and urethanes	They are widely used in furnishings and construction in the form of flexible and rigid foams. The polyol compound reacts with diisocyanate to form a prepolymer	Diisocyanate workers polyurethane manufacturing workers, upholstery workers, spray painters, coating workers ¹⁹ show altered pulmonary functions and asthma along with contact dermatitis	Careful material handling and process ventilation during manufacturing Proper eye, skin and respiratory protection
5. Amino resins	These are thermoset materials used in adhesives, coatings, and insulation materials. They are formed by a chemical reaction of formaldehyde with an amino group	Exposure to formaldehyde causes respiratory and mucous membrane irritation. Release of formaldehyde from finished products may cause air quality problems	Proper ventilation Avoid skin contact
6. Epoxy resins	Used as protective coatings and laminates for metals, woods, and other plastics. Also used as glues, floor coverings, and paints and coatings	Allergic dermatitis and respiratory sensitization is the main health hazard ²⁰	
7. Epichlorohydrin	Used in manufacturing of epoxy resins, glycol, plasticizers, dye-stuffs, lubricants, adhesives, and pharmaceutical products	Epichlorohydrin reacts with nucleic acids and may cause chromosomal aberrations in lymphocytes of exposed workers Dermal contact may cause vesiculated burns Pulmonary exposure may cause pneumonitis ²¹	Minimize the exposure

The tyres produce tremendous quantity of oil, which also contribute to the persistence of fire's persistence. Toxicologically, tyre fires produce tremendous quantities of:

- Particulates
- Heavy metals particularly zinc and lead
- Emission of organics including benzene, toluene, and styrene
- Volatile products of incomplete combustion (PIC)
- Polycyclic aromatic hydrocarbons (PAHs)
- Dioxins and furans. Levels of benzene > 1 ppm in air have been measured within 300 miles of tyre fires.

- Tyre piles are well-known sources of rodent infestations and are common mosquito breeding grounds
- A number of accelerators and other compounds used in the rubber industry– including thiurams; amines; guanidines; disulfides; and certain thiazoles are skin sensitizers causing contact and allergic contact dermatitis in rubber workers²³
- Mucus hypersecretion and mild airway obstruction have been reported in workers exposed to carbon black, additives, talc, and curing fumes. Chronic lung diseases, such as pneumoconiosis, pulmonary fibrosis, bronchitis, and emphysema can occur in workers

exposed chemically to carbon black as well as to dust and particulates.

Medical Surveillance and Prevention

Reduction in the release of air contaminants into the work environment through the use of proper ventilation and substitution of less toxic materials presents a continuing challenge for the rubber industry. As smoking potentiates the effects of some of the chemicals, workplace smoking restrictions policies and smoking cessation programs may be extremely beneficial for rubber workers.

Carcinogenic and Mutagenic Properties of Chemicals

Various chemicals with carcinogenic properties have been identified. Some are carcinogenic to humans, other probable carcinogens, and yet another category comprises of animal carcinogens.

Commonly used accelerators and curing agents (thiuram compounds including tetramethylthiuram disulfide, and tetramethylthiuram monosulfide) have been demonstrated to be carcinogenic.²⁴

Talc, widely used as an anti-tacking agent, is mainly associated with respiratory disease. However, some talcs may contain asbestos fibers and fibrous tremolite.

Carbon blacks contain variable amounts of compounds, some of which have not been identified. The most probable carcinogenic hazard of carbon black is associated with benzene extractable chemicals, consisting mainly of aromatic hydrocarbons and sulfur compounds.

Cancer of the bladder has long been recognized as a problem within the rubber industry and has been associated with specific aromatic hydrocarbons. The cause was probably an organic antioxidant added to the rubber mixture-3-naphthylamine. However, other compounds such as *a*-naphthylamine, benzidine, and 4-aminobiphenyl (xenylamine).

Phthalate Esters

Phthalate esters are plasticizers used in numerous plastic products, including rubber tyres. They contaminate soil and water and are considered weak animal carcinogens.

Curing Fumes and Other Curing Emissions

During vulcanization process, fumes and vapors are emitted into the air because of volatilization of rubber ingredients. Many airborne nitrosamines are formed during rubber processing and are found in the work atmosphere.²⁴

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are fused benzene ring compounds present in crude oil and generated by burning organic materials. The PAHs are found

in aromatic oils, which are extensively used in the rubber industry as plasticizers and softeners. A tyre may contain as much as 20 percent aromatic and paraffin oils.²⁴

The PAHs are potent skin carcinogens in animal models. Normally, in the rubber industry, humans do not frequently come in contact with these aromatic oils. However, uncured rubber, with which workers have much contact, contain large amounts of these oils.

Mineral oils such as coal tar oils, petroleum and other tar products, are widely used in the rubber industry as extenders. The use of mineral oil has also increased over the years because they are cheap and impart desirable properties to the finished rubber. They may induce carcinogenic effects in mammals, including humans. This carcinogenic effect may be due to the presence of the PAHs.²⁵

Nitroso Compounds and Nitrosamines

During vulcanization, air is excluded, and the mold contains a reducing atmosphere. Products that can be formed during vulcanization and released from the surface of the rubber include amines and organic sulfides derived from the accelerators. These compounds demonstrated to be carcinogenic in a number of animal models, have been identified in the extrusion, milling, calendaring, curing, and cooling (post curing) areas of tyre factories.²⁶

Nitroso compounds are divided into nitrosamines and nitro amides. Most of these have been demonstrated to be potent carcinogens. The antidegradent process and curing process and curing process involve amines, nitrosamines, and quinolines, which are suspected carcinogens.

Rubber Industry and Cancer

Various malignancies have been associated with certain jobs in the rubber industry.²⁷

- Malignancies of the lung have been associated with curing jobs
- Malignancies of the lymphatic and hematopoietic system – particularly lymphatic leukemia
- Stomach cancers have been associated with jobs in the production line, including compounding and mixing, milling, and extrusion
- Bladder cancer was one of the first identified cancers in the rubber industry. This is due to B-naphthylamine, which is an accelerator.

The rubber industry employs hundreds of chemicals in a variety of processes, and reactions leading to potentially hazardous exposures can occur in multiple environments. Decomposition products from chemical reactions may account for many unknown exposures to potential carcinogens at various sites with excess lung cancer, leukemia, and lymphomas having been described in certain occupational groups. As a result, control of exposures is an important preventive health issue.

AUTOMOBILE AIRBAG HAZARDS

The deployment of air bag requires a controlled rapid generation of gas within centimeters of the driver's face. In newer vehicles, the same scenario is true for the passengers. This results in the release of products of combustion and creates a unique and potentially hazardous situation within the confines of the passenger compartment. Previously, automotive reactions of this nature were isolated to the engine compartment and, in the case of internal combustion engine, shielded by massive metal blocks. The airbag, however, aims a high-speed chemical reaction of similar intensity directly at the automobile occupant. Instead of massive steel shielding, the airbag offers only the protection of a cloth bag, fiber screens, and a thin metal inflator body. The engineering required to protect humans from this protective device is substantial and impressive.

Most airbags contain sodium azide (N_3Na) salt. This is the major functional component and the one with greatest potential for toxicity. Sodium azide is the primary constituent that reacts to produce the nitrogen gas.

Boron and potassium nitrate are primarily used as the primary ignition material. Nitrocellulose and other materials may be used as enhancers or as autoignition material. Together they ignite the propellant, initiating the chemical reaction that ultimately leads to inflation and off gassing of combustion products.

Source of Exposure

Though there is little or no potential for toxic exposure to sodium azide in automobiles, but toxicity may occur in laboratories and manufacturing plants. Exposure may be through inhalation of azide gas, through hydrolysis in aqueous solutions of the azide salt or from ingestion of the sodium azide salt.

Clinical Features

It may cause respiratory toxicity and pulmonary edema. Methemoglobinemia can occur as a result of oxidation of hemoglobin similar to nitrites.

Signs and symptoms are dose dependant.

- Ingestion of ≤ 40 mg produces headache
- 40 to 60 mg results in syncope and hypotension
- 80 to 150 mg may cause angina, dyspnea, tachycardia, nausea, vomiting, diarrhea, and headache²⁸
- Doses of 1 to 2 g may be fatal.²⁹

In the industrial setting, the two most common routes of exposure are inhalation and skin absorption. Dermal absorption may occur in workers who may tamper with or come in contact with the salt.

However, from a practical perspective, the components of airbag module offer little potential for toxicity. The public is at little risk from any of the chemicals, because the chemicals are sealed in metal and not easily accessible

for tampering. The public's principal risk of exposure is when an airbag is deployed; however, the thermal degradation destroys the modules chemical components and yields principally nitrogen gas with traces of other gases and particulates.

Postdeployment Vehicle Occupant Injury and Toxicity

Orthopedic, ocular, and cardiothoracic injuries and deaths have been associated with airbag deployment. These have even occurred at speeds as low as 15 miles per hour. Such injuries occur because of the physical force of the inflating air bag, which at its maximum speed travels between 50 to 200 mph.³⁰

The most common groups of physical injuries are those that damage the eyes, orbits, and facial structure of the vehicle occupant. Various chemical hazards to automobile occupants can be encountered after activation or deflation of an airbag.

- The airbag is inflated with nitrogen, which is produced when approximately 80 g total of sodium azide is detonated. Powdered residue can produce ocular and nasal irritation. The nitrogen gas is warmed by the explosion, sometimes to temperatures high enough to physically burn the occupant's extremities or face³¹
- Alkaline powder present around the driver's compartment may produce chemical keratitis and other eye burns
- The asthmatics are prone to the aggravation of their pre-existing disease.

Medical Monitoring

Not all workers in the manufacture of airbags need to be medically monitored. Only those employees whose jobs require the use of respirators, that is, those directly involved in the manufacture, grinding, pressing, and to a lesser extent packaging of the explosive components-require monitoring. The physician must perform a medical evaluation, stressing cardiac, pulmonary, auditory, and psychological factors. The employee must be examined for facial deformities, adequate hearing, tympanic membrane rupture, adequate respiratory and cardiovascular function, endocrine disorders, neurologic disorders, and psychological conditions.

HAZARDS OF BIOTECHNOLOGY

Biotechnology is defined as the application of biological systems to technical and industrial processes. This implies the integration of a variety of biological sciences with chemical and process engineering in a way that optimizes the biological system.³²

Applied Microbiology Overview

Applied microbiology has been defined as the use of microorganisms to produce useful products for the benefit

of the mankind. For centuries, yeasts, molds, and bacteria were used to produce meats, fruits, and vegetables and to enhance the quality of life with products including beverages, cheese, bread, foods, and vinegar. Microorganisms are used not only to produce antibiotics, but are also used as tools in basic research and are one of the fields of molecular genetics and molecular biology. A number of industries have been created out of the use of microorganisms as natural factories. The emergence of genetic engineering techniques has allowed us to produce an ever-increasing number and variety of gene products in bacterial and cell cultures.

Biotechnology is the application of biological systems to basic and applied technical and industrial processes. They are all based on the use of microorganisms or cell to serve as a catalyst in the conversion of substrate to product. A concern that is common to all applications is the need to maintain aseptic conditions. This is because all products are made by a pure culture (a population of cells derived from a single strain or clone). To avoid contamination, all phases of the process must be carefully evaluated and monitored.

Biotechnology activity involves the following:

- Isolation and preservation of the organism or cell that is to serve as the biocatalyst or the source of biocatalyst of interest
- Preparation of the biocatalyst
- Process scale up for the biocatalyst or large-scale growth of the microorganism
- Separation of the desired product
- Purification of the product.

Biohazards of the Biotechnology Process

The biotechnology processes may include the isolation of growth medium components, viable and nonviable organisms, and suspended solids. Most reported health problems are associated with downstream processes.³³ Various problems at various levels include:

- Cell separation and disruption processes have the potential to generate substantial aerosols³⁴
- The extraction of intracellular enzymes involves handling large quantities of cell debris and places the greatest demands on biosafety³⁵
- Centrifuges and rotary vacuum filters are also capable of creating contaminated aerosols
- Disruption processes such as ultrafiltration, chromatography, and dialysis are less likely to generate aerosols. However, aerosol generation may occur in the event of failures in seals or piping
- Exposure may also occur during activities such as filling bags, vials, or other containers³³
- With many biological products, the risk of allergic reaction is greatest after the product is more concentrated during purification and packaging³⁵

- The degree of risk may be influenced by the product formulation— whether solid, powder, or liquid form. Effluent from the process may be an additional source of exposure for workers and may have a significant influence on the environment at the point of discharge.³⁴

People at greatest risk are biotechnologists from various disciplines. These disciplines include biochemistry, biology, chemistry, computer science, and medicine.

Types of Hazards

There are three main groups of hazards associated with biotechnology: biological, chemical, and physical hazards.

Biological Hazards

Biological hazards are associated with three properties of microorganisms:

- Potential for a few species to cause illness or disease
- Potential for undetected genotypic or phenotypic changes to alter a tested and approved process
- Ubiquity of the organisms that can contaminate the system.

Aerosols

The health risks associated with biological aerosols depend on the nature of the hazard, the concentration, and on the size and related distribution of the aerosol particles in the lung.

- The size, shape, and density of the particle determine the site of deposition in the body. Bioaerosols from biotechnological process are likely to range in size from individual cells of process organisms to clumps of cells adhered together in a matrix of cultured broth
 - In allergic responses, such as allergy to pollens and molds, larger size and greater concentration of aerosol particles are of significance
 - In airborne infections small particles are significant because of their greater number and the greater probability of being inhaled.³⁶ Single cells and small clumps of cells with an aerodynamic diameter of $< 4 \mu\text{m}$ are capable of penetrating deep into the lung.³⁷
- Stirring or bubbling may lead to formation of thread of film of liquid that can breakdown into small droplets and evaporate into aerosols
- Mixing of culture with pipette, Vortex mirror, and mixer overflow may lead to formation of particles
- Lyophilized cultures if not opened carefully, or dropped or broken may contaminate the environment.

Ubiquity of Organisms

If a contaminant entered that was able to maintain itself, it would disrupt the system in several ways.

- By direct interference or inhibition of the biocatalyst (enzyme, cell, or microorganism)

- It could destroy the catalyst or the product by using it as an energy source
- The contaminant could induce substances that are difficult to separate from the product, thereby rendering the product unusable.

Various local barriers in biotechnology laboratories and included in Table 3:³⁸

Chemical Exposure to the Biotechnology Industry (Table 4)

Common operations of biotechnology include gel electrophoresis, high-performance liquid chromatography (HPLC), and protein and nucleic acid engineering. Some of the commonly used chemicals with toxic properties are enlisted below:

- *Acetonitrile*: It is a common solvent and extractant used by biotechnologists for HPLC. It is toxic by any route of exposure, and massive exposures have been reported to cause death by cyanide asphyxiation after inhalation in workplaces. Survivors of acute exposure suffer from a variety of reversible symptoms and findings affecting the central nervous system, blood, and possibly kidneys.³⁹ Exposure to small quantities may cause malaise, nausea, and headache.
- *Methylene chloride*: It is a multipurpose solvent, used to remove paint or grease. It is a recognized animal and possibly human carcinogen.⁴⁰ It is particularly toxic for paint strippers as they are exposed to higher doses of the chemical.
- *Tetramethylenediamine*: This chemical is used in gel electrophoresis to examine DNA fragments. It is an eye irritant as well as potential sensitizer. It is known to be mutagenic.
- *Acrylamide*: It is a white crystalline powder used to make polyacrylamide gel. Researchers have made up their own gels from acrylamide powder, with potential for dust exposure during weighing, transferring, and mixing operations. Acrylamide is the second most common potential source of toxic exposure for biotechnology researchers, including skin contact with powder and with gel preparations. Dermal absorption at high doses may cause neurotoxicity in the form of symmetric progressive distal neuropathy. Contact dermatitis of the palms may precede the neurological syndrome. Acrylamide also causes

direct testicular degeneration in exposed rodents⁴¹ and is recognized as a genotoxin with primary mechanisms of heritable translocations and spermatocytosomal clastogenesis.

Given the toxicity of acrylamide, it is essential to formulate certain policies to reduce acrylamide exposure. They include:

- Source reduction: purchase in smallest container in amount required. This would not only reduce the waste disposal, but also the preparation may be mixed without weighing
- Weigh out in tarred closable containers in fume hood. This reduces the exposure during weighing
- Purchases in solution reduce the skin exposure
- By using ventilated groove box or hood with a dedicated balance, bottle is opened only under local exhaust
- Use gloves to prevent skin exposure.
- Chilled water is used to meet the precise temperature and humidity conditions required for cell line production. Chemical hazards of chilled water maintenance unit include exposure to a variety of corrosive or sensitizing elements, including strong alkaline and acid chemicals, amines, and hepatotoxic chemicals, such as dimethylformide. Recirculating chilled-water units also pose a potential nuisance odor hazard. Such units often contain antifreeze additives such as ethylene glycol. Foul-smelling bacteria, such as *Clostridium glycoliticum*, may metabolize antifreeze within standing chilled-water during intervals between the operations. Any break in chilled water pipes releases the odorous metabolites. Recirculating chilled water is also a source of *Legionella pneumophila*, responsible for Legionnaire's disease.⁴² Prevention of this work-related illness requires frequent biocidal treatments and routine microbiological sampling of treated water.

Physical Hazards

Biotechnology is a dynamic industry. Various physical hazards of production activities are given in Table 5.

Medical Surveillance

Medical surveillance of workers involves the collection and use of medical information, biological monitoring, medical screening, or other health data for developing strategies for the prevention of disease. Biological monitoring is the use of tests of body fluids or skin to indicate exposure, and medical screening is the early detection of a health effect to prevent overt disease or to increase chances of recovery.

The purpose of periodic monitoring of biotechnology work include detecting evidence of exposure to biological or chemical hazards, detecting early clinical signs or symptoms of disease, assessing control measures,

Table 4: Impact of metals and other chemicals

<i>Metals</i>				
<i>Metal</i>	<i>Use</i>	<i>Acute exposure</i>	<i>Chronic exposure</i>	<i>Preventive measures</i>
Beryllium	Exposure occurs during melting, grinding, buffing, and general lathing operations of beryllium containing alloys	High concentrations may cause irritation of the eyes, and respiratory tract	Delayed-onset pulmonary granulomatosis and damage to liver, kidney, and circulatory system, dermatitis, and skin ulcers	<ol style="list-style-type: none"> 1. Proper protective gloves, eye protection, and masks should be worn during casting, polishing, or grinding 2. Use power suction methods for cleaning 3. Dispose of wastes and contaminated clothing properly
Mercury	Exposure occurs through the contact or handling of mercury and its compounds, inhalation of vapors or respirable dusts. Accidental spillage may occur	High mercury accumulation, evidenced by X-ray fluorescence of the head and wrist (>40 µg/g), led to neurological and neuropsychological as well as visual problems	Chronic mercurism may cause loss of appetite, nausea, diarrhea, speech disorders, mucosal ulcers, gingivitis, CNS disturbances, nephritis, thrombocytopenia, and aplastic anemias	<ol style="list-style-type: none"> 1. Adequate ventilation 2. Office monitoring of mercury vapor 3. Personal monitoring 4. Biological evaluation of dental personnel 5. Use water spray and suction while grinding amalgam 6. Use sealed amalgam capsules 7. Proper mercury storage 8. Clean spills immediately 9. Avoid skin exposure
Nickel	Used in production of prosthetic devices. Exposure occurs by inhalation or ingestion of dust produced during grinding	Irritation to the eyes, mucous membranes, and respiratory tract	It is a potential carcinogen causing lung and nasal cancer	<ol style="list-style-type: none"> 1. Use protective gloves eyewear, and masks when fabricating or grinding nickel-containing alloys 2. Use high-velocity evacuation systems⁴⁵
<i>Other Chemicals</i>				
<i>Name</i>	<i>Source of exposure</i>	<i>Health effects</i>	<i>Preventive measures</i>	
Acetic acid	Photographic solutions	Eye, nose, throat, and skin irritation; bronchitis; skin and eye burns	<ol style="list-style-type: none"> 1. Use protective gloves and eyewear. Wash skin or eye contact immediately with running water 2. Adequate ventilation 3. If spill occurs use soda lime or commercial acid spill 4. Use forceps to handle any object in acid, avoid splashing 	
Chlorine	Disinfectant	Eye, nose, throat, mucous membrane, and skin irritation; bronchitis; dermatitis; and dental erosion	Wear proper protective eyewear and gloves	
Ethylene oxide	Sterilizing agents	Skin, respiratory and eye irritation; skin sensitization; peritoneal cancer; leukemia; adverse reproductive effects	<ol style="list-style-type: none"> 1. Direct exhaust from sterilizers to an outdoor location 2. Ensure use of interlocks to prevent opening of sterilizers while they are being operated 3. Use protective gloves and forceps to remove things from sterilizers 4. Strictly control the source of ignition 	
Glutaraldehyde	Sterilizing agents	Eye, nose, and throat irritation; dermatitis; contact with eye may cause severe burns	Wear protective gloves	

Contd...

Hydroquinone	Methacrylate and denture base resins; photographic solutions	Eye and skin irritation, conjunctivitis and keratitis	Wear protective eyewear and gloves
Methyl methacrylate	Denture base resins	Eye, mucous membrane, respiratory, and skin irritation; dermatitis	Wear proper protective eyewear and gloves
Phenol	Disinfectant	Mouth, nose, throat, and skin irritation; liver and kidney damage; severe skin burns from contact	Wear proper protective gloves. If potential for high exposures is present, wear NIOSH approved mask
Latex	Used in gloves	Hypersensitivity to latex may cause skin problems	Use vinyl, neoprene, or other latex substitute gloves
Soaps and detergents	On average dental personnel wash their hands 15 times a day	Contact dermatitis due to destruction of protective layer of epidermis	Use hand cleaners, which do not contain abrasives, defat the skin, cause allergic sensitization, and breakdown with storage
Ionizing radiation	Radiological exposure	Radiation exposure may rarely cause leukemia and shortened life span	Judicious use of X-rays and more sensitive fast-speed films, and better techniques

Table 5: Physical hazards of production activities

Type	Source
Burn	Pressurized steam, liquid nitrogen/acetone/dry ice
Hypothermia	Cold room (up to 12 hours continuously)
Electrical	Heavy equipment, electrophoresis units
Cuts	Glass bottles, glass bioreactors
Anoxic	CO ₂ and N ₂ lines
Ergonomic	Drums, large bottles, media preparation, and other scaled-up equipment
Repetitive trauma	Computer modeling
Shift work	24-hour microbial support (monitoring) of large-scale production; product isolation and purification

detecting changes in employee health status, and identifying patterns of disease indicating a workplace exposure. The periodic evaluations should focus on changes from the baseline exam as a result of potential exposures, such as the development of allergy or signs or symptoms of adverse effects of infectious agents or biologically active agents.

Primary Prevention

In the biotechnology industry, primary prevention is by hazard control, safe work practices, and immunizations. When working with biological agents, two key components of a medical surveillance program are determining the immune status of the employee and eliciting the employee's vaccination history. Because many of the biological agents are opportunistic pathogens, an individual

whose immune status is compromised should be advised to refrain from working with them. Employees should be offered vaccinations if available for the agents in use. All employees exposed to blood, body fluids, or tissue cultures should be offered hepatitis B vaccination.⁴³ Various underlying disease conditions that require screening include:

- Conditions that could interfere with the immune system including, steroid treatment for various medical conditions, or immunosuppressive therapy for cancer or connective tissue diseases, acute viral infections, poorly controlled diabetes, severe alcoholism and pregnancy.
- Workers with chronic dermatitis, eczema, or psoriasis have an increased susceptibility to infection because of altered cutaneous defenses and therefore must wear gloves or avoid exposure to potentially infectious agents.⁴⁴

Product Hazards

Biotechnology workers in fermentation or cell culture production areas with purification processes encounter risks of adrenocortical suppression,⁴⁴ gynecomastia in male workers and menstrual bleeding in female workers.

Control Measures

Containment represents the integration of personnel procedures and practices with laboratory design and engineering features to minimize the exposure of workers to hazardous or potentially hazardous agents or substances.

Personnel Practices

- When entry restrictions are necessary, a hazard warning sign incorporating the universal biohazard symbol should be posted on all access doors to restricted area

- Supervisions should prohibit smoking, eating, and drinking as inadvertent ingestion is a potential route of exposure to microorganisms
- Strict hand washing
- Use mechanical pipetting devices
- Use of appropriate gloves, face protectors, and laboratory clothing
- Well-defined housekeeping procedures and schedules are important in reducing the risks.

Laboratory Practices

- Work surfaces must be decontaminated daily and immediately after spills
- All biological waste and contaminated equipment should be decontaminated or inactivated before disposal or reuse
- Hypodermic needles and syringes should be used carefully. Use needle-locking syringes or units
- Contaminated broken glass also is a potential hazard, which must be decontaminated and disposed off carefully
- Safety devices that prevent the escape of aerosols into laboratory environment, including biological safety cabinets should be used.

DENTAL HEALTH CARE HAZARDS

Dentists and dental health professionals comprise a sizable group at risk for multiple occupational exposures. Unacceptable hazards and exposures including excessive amounts of mercury and waste anesthetic gases in the environment have been found in a number of dental offices and clinics.

Chemical Agents

During routine practice of dentistry, dentists and dental personnel are at risk for multiple exposures to chemical agents. Although benign for most dental patients, prolonged or repeated exposures may lead to adverse health effects to the dental staff. Acute exposures from chemical releases in the workplace are also a matter of concern. Dental personnel can inadvertently inhale waste anesthetic gases, the long-term exposure to which has been associated with a variety of deleterious health effects. Finally, a number of health consequences may result after exposure to certain disinfectants, sterilants, and photographic materials.

Waste Anesthetic Gases

Administration of inhalation anesthesia in dental operations has resulted in considerable exposure of dental personnel to waste anesthetic agents. These gases include nitrous oxide, halothane, enflurane, and others. Reported effects in humans include decrements in motor, perceptual,

and cognitive skills, liver disease, cancer, spontaneous abortion, and birth defects in offspring.

Exposure to waste anesthetic gases occurs primarily from leakage of gases from anesthetic system, poor fit of the mask on patients, and improper work practices. To provide a safer workplace for those at risk for exposure to waste anesthetic gases, the following preventive measures should be implemented:

- Use effective scavenging equipment and monitoring devices
- Regularly inspect anesthetic administration equipment from leaks
- Direct waste gas away from windows, ventilators, air-conditioning inlets, or other areas that might allow gases back into the office
- Maintain adequate ventilation
- Minimize conversation with patients
- Check for snug fit of facemask
- Maintain and service equipment regularly.

Mineral Dusts (Airborne Particulates)

Clinical dental procedures, such as high-speed grinding of silica-containing composite restoratives, the contouring of fused porcelain, and the polishing of plastics and metals with silica- or metallic oxide-containing materials, are routine in the dental work environment.

Asbestos has been used chiefly as a binder in periodontal dressings and as a lining material for casting rings and crucibles. Airborne asbestos is known to cause pulmonary fibrosis (i.e. asbestosis), lung cancer, and mesothelioma of the pleura and peritoneum.

CONSTRUCTION WORKERS

Construction workers build, repair, renovate, modify, and demolish structures of all sorts and in industrialized nations, where construction is ranked amongst the most dangerous occupation; large numbers of teenagers are employed for these jobs. These workers are more like nomads moving wherever the construction boom is. They also tend to live in make shift houses/*jhuggis* and their children also tend to play near construction sites and are thus exposed to the same hazards as the workers.⁴⁶

Construction is often done in extreme heat or cold, in windy, rainy, smoggy, or foggy weather, or at night. Health care facilities are limited for such workers, and even those who desire health care, episodic employment, frequent changes of employer, and continuous changes in work site exposures and ambient conditions limit the clinician's or the researcher's ability to trace the individuals work history or exposures to hazards.⁴⁷ Because of these factors, many of which are unique to construction, limited data exist on the extent or effect of toxic exposure in the construction industry.

Lead Toxicity

High-risk activities associated with lead dust and fumes amongst bridge and structural steel workers: abrasive blasting, sanding, burning, cutting or welding on steel structures coated with lead paint, and the use of containment enclosures at these sites could result in high lead concentrations, and hence toxicity.

There are various mechanisms by which lead interferes with normal function. These include binding and interfering with the function of many proteins of the sulfhydryl group. Some of these changes may occur at extremely low concentrations of lead. For instance, protoporphyrinogen synthetase, an enzyme is extremely sensitive to lead.⁴⁸ Other enzymes affected are guanine hydroxylase, ferrochelatase, and 5'-pyrimidine nucleotidase.⁴⁹ Lead affects the central nervous system, and may accumulate in the kidney leading to Fanconi's syndrome.⁵⁰ Chronic lead poisoning is associated with gouty nephropathy and renal failure in adults.

PAPER AND PULP INDUSTRY

A whole range of acute and chronic lung diseases and a variety of annoyance symptoms (including headaches, nausea, eyes and throat irritation) are common in workers of paper and pulp industry. Odorous pulp mill air emissions are probably responsible for annoyance reactions. However, hydrogen sulfide, mercaptans, and organic sulfides are capable of producing respiratory tract and mucous membrane irritation at lower exposure levels.

The occupational health status of pulp mill workers has been studied for a variety of endpoints, including cancer, pulmonary function, skin diseases, and hearing impairment. Community studies of chronic respiratory disease (in particular, bronchitis) near pulp mills have typically shown excesses in relationship to smoking and mill employment, but not to residents living in proximity to the mills.⁵¹

Cancer mortality patterns among pulp mill workers have been examined in a number of cohort studies—yielding proportional mortality ratios and standardized mortality ratios and in case control studies and tumor registry-based standardized incidence ratio studies.⁵²

Finally, a variety of cutaneous hazards also exist in pulp mills, including wet work and botanical allergent, phototoxic chemicals (e.g. anthraquinone) used in delignification, and cutaneous irritants used in slimicides.⁵³

EMERGING INFECTIOUS DISEASES

The classification of new pathogenic agents has been accompanied by the discovery that infectious agents are associated with a number of diseases that have not been classically considered infectious. Many malignancies result

from chronic infections, including lymphoma, and nasopharyngeal carcinoma (Epstein Bar virus), human T-cell leukemia/lymphoma virus-1, liver cancer (hepatitis B and C), cervical carcinoma (human papilloma virus), stomach cancer (*Helicobacter pylori*), and Kaposi's sarcoma (HHV-8).

Categories of Emerging Infections

New Infections

HIV originated in central Africa and spread occurred through heterosexual transmission of the infection. In contrast, the epidemics of the United States and Western Europe began predominantly as infection of male heterosexuals and were rapidly followed by its spread among parenteral drug users, with relatively limited spread into the remainder of the population. In India, the proliferation of the HIV epidemic has followed the major truck routes, with truck drivers acquiring the infection via their contact with the prostitutes, followed by transmission to prostitutes in their communities as well as transmission within the communities in which they live.⁵⁴

Remerging Diseases

Many infectious diseases are characterized by epidemic occurrence with substantial variation in incidence over months, years, or decades. Seasonality occurs when the variation is annual and is found in infections caused by influenza, enteroviral, malaria, tick-borne, and numerous others. There are multiple reasons for emergence or re-emergence of these infections, which include:

Ecological Factors

A number of diverse ecological factors may be important in the emergence of infectious diseases, and they have been enlisted in the beginning of the chapter. One of the more frequent examples involves changes that result in closer proximity between humans and vectors or animal hosts of zoonotic infections.

Climatic changes have a variety of effects on infectious disease transmission.

- In sub-Saharan Africa, epidemic transmission of meningococcal meningitis occurs during the dry season.⁵⁵
- Malaria transmission is more intense in rainy season because of proliferation of anopheline mosquitoes. The *Plasmodium* parasites are limited to temperatures of greater than 16°C, and the incubation period of the mosquito is shortened as the temperature rises to 27°C. During the twentieth century, the earth's mean temperature has risen by 0.5°C.

Even earthquakes can have an important effect on infectious disease transmission, as demonstrated by a large outbreak of coccidioidomycosis in Ventura County, California, after an earthquake that occurred in 1994.⁵⁶ The earthquake allowed the fungus to be carried by dust

clouds into an area that normally has very little coccidiodomycosis.

Microbial Adaptation

- Isolates of *S. aureus* resistant to the antistaphylococcal penicillins (e.g. methicillin) have spread throughout the world and are frequent in some regions. Other organisms for which drug resistance has become an important problem include *Plasmodium falciparum*, *Plasmodium vivax*, *Mycobacterium tuberculosis*, *Streptococcus pneumoniae*, and *Enterococcus faecium*.
- Organisms may also acquire new virulence factors by acquisition of the gene from other organisms or by mutation of existing genes. Probable examples of this include toxic shock production by *S. aureus* or *Streptococcus pyogenes*. HIV most likely adapted to humans from another primate host and is even able to adapt to different cell types within an individual human host because of its rapid mutation rate.

Human Behavior

- The plague epidemic of the Middle Ages resulted in part from the crowded substandard living conditions that brought people in close proximity with rats and with each other.
- In the last half of the twentieth century, the sexual revolution in the United States and elsewhere, with its concomitant increase in numbers of sexual partners, led to increased frequencies of a number of sexually transmitted infections, including *Chlamydia trachomatis*, HPV, HSV, and HIV.
- Human diets play an important role. Enteric and systemic pathogens that are commonly transmitted by food include *E. coli*, *Campylobacter jejuni*, *Shigella* sp., *Salmonella* sp., *Trichinella spiralis*, and numerous others.
- The epidemic of transmissible neurodegenerative disease in the United Kingdom most likely resulted because cows fed on the remains of other cows who had died from bovine spongiform encephalopathy (BSE), resulting in a high prevalence of BSE in cattle; then, people were rarely infected after ingestion of meat from these cattle.

Breakdown in Public Health

- The decreased mortality from infectious diseases in developed countries during the twentieth century has resulted far more from improved hygiene and public health measures than from the use of antimicrobial agents.
- The substantial increases in frequency and morbidity from pertussis that occurred in Europe and North America when the fear of vaccine side effects resulted in low immunization rates in entire populations.
- Revolution and war in many countries have led to a high number of refugees living in conditions of poor

hygiene, resulting in a high incidence of cholera and other enterically transmitted infections.

- The dismantling of the tuberculosis control program in the United States has played an important role in the current resurgence of tuberculosis.

Eventually environment continues to affect the welfare and health of individuals and populations into the twenty first century. Politics and economics will either continue to cloud science in the debate on environmental pollution and the interrelated health of humans and ecosystems or will help to clarify the facts and provide answers to pollution problems.

Multidisciplinary research will better define the interdependent relationship between environment and health. Finally, better economic modeling inclusive of natural capital and "silent" ecosystem markets will be critical to reinvesting in the environment.

Another important issue which has changed the dimension as well as horizon of medical problems is globalization. Hence, it is pertinent that we mention how globalization impacts human health.

- The globalization of trade is particularly relevant for health services that have become a commodity that can be traded in distinct ways. First, health services can be provided across borders. Examples include a range of telemedicine tools, such as teleradiology and teleradiology as well as medical consultation through traditional and electronic channels. Second, patients can travel abroad to receive health care or use certain facilities.⁵⁷ Other countries, including developing ones such as Cuba and India, openly advertise to attract foreign patients to their clinics and hospitals.⁵⁸
- Globalization has had large effects on international travel, with serious consequences for global health. The liberalization of the airline industry in many countries has made air travel affordable for more and more people around the world, which has led to a dramatic increase in the amount of global air travel. Sutherst⁵⁹ estimated that about one million people travel internationally every day and a similar number travel between developed and developing countries each week. Far-reaching air travel, aided by improvements in aircraft technology that allow longer non-stop flights, facilitates the spread of communicable diseases. It is entirely possible that a person in the early stages of an infectious disease could be halfway around the world in 12 to 15 hours and thus function as a vector for that disease, aiding its spread, perhaps into vulnerable and nonimmune populations. The recent epidemic of severe acute respiratory syndrome (SARS) is the best contemporary example of the rapid spread of a hitherto unknown and virulent viral pathogen through travel of infected humans⁶⁰
- Another example is the global spread of antibiotic-resistant *Pneumococcus* that was first identified in Spain

in the early 1980s and rapidly jumped to South Africa and the USA before spreading to all other parts of the world.⁶¹ Each year, approximately two million children die in developing countries as a result of lower respiratory infections, mostly pneumonia. The exact origin of this *Pneumococcus* strain is still unknown but is likely to come from the Far East⁶²

- Giving basically everyone who is interested access to the full sequences of human pathogen genomes, and the ongoing trend towards open access of published research⁶³ and even ongoing research activities for new drugs⁶⁴ poses a serious dilemma with important implications for global health. Should the full sequence of the anthrax bacillus or smallpox virus and other virulent pathogens be published if this data could be used to develop biological weapons?

Anticipatory Guidance in Pediatric Oral Health

Kishore Shetty, Bhavini Acharya, Michael Higgins

INTRODUCTION

To ensure a smooth transition from one stage in the growth and development of a child to the next, parents and care givers can take specific action. The health care in the first few years of a child's life, the formative years, is very essential to the long-term health of that child. Health professionals can educate and train parents to monitor the overall health of the child and can guide them through these critical years. Oral health is a vital part of overall infant health. All individuals with whom a child interacts play an important role in the overall health and development of the child, including the child's family, dentists, pediatricians, and other health professionals. These providers can work together towards a common goal of improving the child's oral health and, in turn, general health. To achieve this goal health professionals should provide to parents, anticipatory guidance, which would help them better care for their children's health because anticipatory guidance, much as the name implies, anticipates oral issues and diseases and incorporates a preventive regimen into the child's health care. To achieve effective anticipatory guidance, providers must have guidelines on which to base prevention and early treatment strategies. The oral health of children in developed and developing countries has significantly improved over the years, but high-risk groups into which prevention and intervention strategies have not been extended still exist, including families with low-income or without health insurance, minority groups, and children with special health care needs, because of a lack of pediatric dentists in some areas, no access to affordable dental care, and a lack of the parent's knowledge about when and why to see a dental professional.

The American Association of Pediatric Dentistry (AAPD) puts special emphasis on anticipatory guidance in pediatric oral health. The risk-benefit ratios and cost-effectiveness of preventive procedures in developing

countries indicate that anticipating and preventing health problems are more economical for both the individual and the government. Countries other than the United States that have guidelines similar to those of the AAPD have reduced the prevalence of many oral diseases, especially dental caries.¹ This reduction is very important because even in a developed country like the US dental caries is the most common childhood disease and 5 times more common than asthma.²

Anticipatory Guidance for the Health Professional

The AAPD and the American Dental Association (ADA) recommend that a child should first visit the dentist within six months of eruption of the first tooth and no later than 12 months of age.⁴ After that, a child should visit a dentist every 6 months or according to the individual need of the child. The reason for the first-year dental visit is for the parent to receive oral anticipatory guidance and to establish a "dental home", which identifies a child with a dentist in a familiar and safe health-supervision relationship and is similar to that of a "medical home."⁵ The medical home is where a child's parent receives prevention instructions, counseling and anticipatory guidance, and where a child receives medical care such as immunizations. A medical home can also provide an oral health exam and referral to a dentist, which can result in a dental home for the child at an early age, a practice that the AAPD recommends.³ A dental home can provide orodental anticipatory guidance for parents of a child as young as the age of 1 and provide access to preventive and emergency services.

The concept of dental home is new and though no empirical data have been gathered. Table 1 shows the ideal characteristics of a dental home.⁵ In addition scientific evidence supports the reasons for the child's first visit within the first year. For example, *Streptococcus mutans* has been detected as early as 6 months of age in preeruptate

Table 1: Ideal characteristics and practical advantages of a dental home

<i>Characteristic</i>	<i>Description</i>	<i>Practical advantages</i>
Accessible	<ul style="list-style-type: none"> Care provided in the child's community All insurance accepted and changes in coverage accommodated 	<ul style="list-style-type: none"> Source of care is close to home and accessible to family Minimal hassle encountered with payment Office ready for treatment in emergency situations Office nonbiased in dealing with children with special health care needs Dentist knows community needs and resources (like fluoride in water)
Family centered	<ul style="list-style-type: none"> Recognition of centeredness of family Unbiased complete information is shared on an ongoing basis 	<ul style="list-style-type: none"> Low parent child anxiety improves care Care protocols are comfortable to family (behavior management) Appropriate role of parents in home care is established
Continuous	<ul style="list-style-type: none"> Same primary care provider from infancy through adolescence Assistance provided with transitions (for example, to school) 	<ul style="list-style-type: none"> Appropriate recall intervals are based on child's needs Continuity of care is better owing to the recall system Coordination of complex dental treatment is possible (traumatic injury) Liaison with medical providers for CSHCN is improved (congenital heart disease)
Comprehensive	<ul style="list-style-type: none"> Health care available 24 hours a day 7 days a week Preventive, primary and tertiary care provided Information centralized 	<ul style="list-style-type: none"> Emergency access is ensured Care manager and primary care dentist are in the same place
Coordinated	<ul style="list-style-type: none"> Families linked to support education and community services 	<ul style="list-style-type: none"> Records centralized School, workshop, therapy linkages established and known (cleft palate care)
Compassionate	<ul style="list-style-type: none"> Expressed and demonstrated concern for child 	<ul style="list-style-type: none"> Dentist-child relationship is established Family relationship is established Children less anxious owing to familiarity
Culturally competent	<ul style="list-style-type: none"> Cultural background recognized, valued and respected 	<ul style="list-style-type: none"> Mechanism is established for communication of ongoing care Specialized resources are known and proven if needed Staff may speak different languages and know dental terminology

Adapted from: The Dental Home – A Primary Care Oral Health Concept, Arthur J. Nowak; Paul S. Casamassimo JADA Vol. 133, Jan 2002.

children; the mother was the source of the infection.⁶ This first visit is therefore an opportunity for the dentist to instruct the parent on oral health practices for the child. Such a home could be a foundation on which a lifetime of preventive dental education and care can be built.

In the United States 66 percent of children ages 2 to 4 years old from families with annual incomes of less than \$10,000 had not had a dental visit the preceding year.⁷ The AAPD suggests that if pediatricians learned about and promoted oral health of infants and children pediatricians could educate parents and children and work in partnership with oral health professionals. As part of routine oral-supervision visits pediatricians can incorporate interview questions, risk assessment, screening and anticipatory guidance.³ These interview questions address dietary practices, fluoride exposure, oral hygiene, utilization of dental services, number and location of mother's

fillings and other dental work. The pediatrician can then provide to the dentist a good baseline on the risk of oral disease in the child and help the dentist better educate the parents in the dental home.

The pediatrician should begin a dental risk assessment by the age of 6 months though all children are not at equal risk of developing dental problems. Tables 2 to 5 shows the risk factors and protective factors for four common diseases of childhood, i.e. dental caries, periodontal disease, malocclusion, and injury and these could be a guide on which prevention strategies can be based.¹⁴ Oral screenings and examinations will reveal if tooth eruption and loss are on schedule. Although variations in tooth eruption and loss can be normal, these variations may also indicate oral health problems. For example, delayed tooth eruption can be due to certain syndromes, developmental defects of teeth, cysts, or tumors. Screening also assesses

tooth irregularities and alignment of teeth and will help find problems early and prevent any further harm to the dentition. In addition, the pediatrician can assess the parent's administration of oral hygiene practices and demonstrate

proper practices to the parent, such as the correct plaque removal technique with an appropriate-sized toothbrush. This visit can also address tooth decay, malocclusions, oral injuries, and other risk factors for each child.

Table 2: Risk assessment for different childhood dental conditions—dental caries

<i>Risk factors</i>	<i>Protective factors</i>
<p><i>All ages</i></p> <ul style="list-style-type: none"> • Inadequate oral hygiene • Poor family oral health • Poverty • Frequent snacking • Special carbohydrate diet • Frequent intake of sugared medications • Reduced saliva flow from medication or irradiation • Variations in tooth enamel; deep pits and fissures; anatomically susceptible areas • Special health needs • Previous caries experience • Gastric reflux • High mutans streptococci count 	<ul style="list-style-type: none"> • Optimal systemic and/or topical fluoride • Good oral hygiene • Access to care and good oral hygiene • Access to care • Reduction in snacking frequency • Preventive intervention to minimize effects • Alternative medications or preventive intervention to minimize effects • Saliva substitutes • Sealants (if possible) or observation • Preventive intervention to minimize effects • Increased frequency of supervision visits • Management of condition • Reduction of mutans streptococci
<p><i>Early childhood</i></p> <ul style="list-style-type: none"> • Bottle use at night while sleeping or when awake at will • High parental levels of bacteria (<i>S. mutans</i>) • History of baby bottle tooth decay 	<ul style="list-style-type: none"> • Prevention of bottle habit and weaning from bottle at 12 months • Good parental oral health and hygiene • Increased frequency of supervision visits
<p><i>Infancy</i></p> <ul style="list-style-type: none"> • Bottle use at night while sleeping or when awake at will • High parental levels of bacteria (<i>S. mutans</i>) • History of baby bottle tooth decay 	<ul style="list-style-type: none"> • Prevention of bottle habit and weaning from bottle at 12 months • Good parental oral health and hygiene

Table 3: Risk assessment for childhood dental conditions—periodontal disease

<i>Risk factors</i>	<i>Protective factors</i>
<p><i>All ages</i></p> <ul style="list-style-type: none"> • Inadequate oral hygiene • Unrestored caries • Poor family oral health • Poverty • Special health needs • Nutritional deficiency • Infectious disease • Medications • Metabolic disease • Neoplastic disease • Genetic predisposition • Poor quality fillings • Mouth breathing • Injury 	<ul style="list-style-type: none"> • Good oral hygiene • Restoration of carious lesions • Access to care and good oral hygiene • Access to care • Preventive intervention to minimize effects • Healthy eating habits • Treatment of disease or preventive intervention to minimize effects • Preventive intervention to minimize effects • Treatment of disease • Treatment of disease or preventive intervention to minimize effects • Preventive intervention to minimize effects • Properly contoured and finished restorations • Management of condition • Use of age appropriate safety measures and treatment of injury
<p><i>Early childhood</i></p> <ul style="list-style-type: none"> • Malpositioned and crowded teeth 	<ul style="list-style-type: none"> • Good oral hygiene
<p><i>Infancy</i></p>	
<p>None</p>	<p>None</p>

Table 4: Risk assessment for different childhood dental conditions—malocclusion

<i>Risk factors</i>	<i>Protective factors</i>
<i>All ages</i>	<ul style="list-style-type: none"> • Early intervention • Early intervention • Early intervention • Use of age appropriate safety measures • Dental intervention as part of medical care • Early intervention • Dental intervention as part of medical care • Dental intervention as part of medical care
<ul style="list-style-type: none"> • Congenital absence of teeth • Variations in development (tooth eruption delays and malpositioned teeth) • Conditions associated with malocclusion (e.g. cleft lip/palate) • Injury • Acquired condition from systemic condition or it's therapy • Family tendency toward malocclusion • Musculoskeletal conditions (e.g. cerebral palsy) • Skeletal growth disorders (e.g. renal disease) 	
<i>Early childhood</i>	<ul style="list-style-type: none"> • Elimination of habit • Early therapy • Early intervention for caries
<ul style="list-style-type: none"> • Non-nutritive sucking habits • Muscular imbalances • Loss of space due to caries 	
<i>Infancy</i>	
None	

Table 5: Risk assessment for different childhood dental conditions—injuries

<i>Risk factors</i>	<i>Protective factors</i>
<i>All ages</i>	<ul style="list-style-type: none"> • Referral for counseling • Referral for counseling • Referral for counseling • Referral for appropriate therapy • Use of age appropriate safety measures
<ul style="list-style-type: none"> • Substance abuse in family • Child abuse or neglect • Multiple family problems • Lack of protective reflexes 	
<i>Early childhood</i>	<ul style="list-style-type: none"> • Orthodontic care • Referral for appropriate therapy • Adjustment of medications • Management of condition
<ul style="list-style-type: none"> • Failure to use safety measures appropriate for child (like car safety seats, stair gates, safety belts) • Protruding front teeth • Poor coordination • Over medication • Hyperactivity 	
<i>Infancy</i>	
<ul style="list-style-type: none"> • Failure to use safety measures appropriate for infant (like car safety seats, stair gates, safety belts) 	<ul style="list-style-type: none"> • Use of age appropriate safety measures

The pediatrician can screen a child and refer the child to a dentist, who can establish a dental home for the child. An oral examination by a dentist includes a complete clinical oral assessment and appropriate diagnostic testing to assess oral growth and development and/or pathology. During the exam the dentist will also assess the child's exposure to topical and systemic fluoride, counsel parents about fluoride, and prescribe systemic fluoride supplements, if indicated. In this visit the dentist will also assess the appropriateness of feeding practices and provide anticipatory guidance. If stains or deposits are present, the dentist or dental hygienist may remove them and schedule another appointment if the child needs further treatment. The first visit will also help familiarize the child

to a dental office and can make the child more receptive to dental care.³

Recommendations

Anticipatory guidance can identify and prevent problems because dentists can treat many oral diseases and conditions if they are identified early in their development. The AAPD recommends that all primary health care professionals who serve mothers and infants should provide parent/caregiver education on the etiology and prevention of early childhood caries (ECC). Oral health counseling is especially important for the mother. Therefore, materials on the infectious and transmissible nature of bacteria that cause ECC and methods of oral health risk assessment,

anticipatory guidance, and early intervention should be in the curriculum of all medical, nursing and allied health professional programs.³

By six months of age every infant should receive an oral health risk assessment from a dentist or pediatrician.³ This risk assessment should include the use of the caries assessment tool (CAT), shown in Table 6, to determine the patient's risk of developing ECC, education on infant oral health, and should evaluate and optimize fluoride exposure. This should all be part of establishing a dental home for the child, and the dentist can use this information to determine a timetable for future appointments for the child.

The pediatrician should advise parents or caregivers to establish a dental home for infants by 12 months of age;⁴ in this visit the dentist should record thorough dental and medical histories of mothers/caregivers and infants and perform a thorough oral exam.

Besides doing the risk assessment the pediatrician can also work with the child's dentist and help plan comprehensive care and appropriate interventions as necessary. For example, if the pediatrician notices a lot of decay in a child he can make the necessary referral for restoration and also provide a background on the child's medical health to help dentist plan treatment accordingly.

Anticipatory Guidance and Pediatricians and Dentists

The AAPD has recommendations for pediatricians and dentists on educating parents on the oral developmental changes of their children and parental care for them at every stage. Included here are recommendations for expectant mothers, parents of infants and young children, which can be in a dental home environment (Table 7).

Pregnant Women, New Mothers or Intimate Care Givers

Pregnancy is a good stage for physicians to instill appropriate oral hygiene practices in expectant mothers. Physicians should advise them to brush their teeth thoroughly twice a day with fluoridated toothpaste and spit out the excess after brushing and to floss daily. The residual toothpaste helps prevent tooth decay. Expectant mothers should rinse every night with an alcohol-free over-the-counter fluoridated mouth rinse. They should have a dental visit for an exam and restoration of all active decay as soon as feasible. The physician should also educate the mother about hormonal changes during pregnancy, which can increase a woman's risk for gingivitis.

Table 6: AAPD caries risk assessment tool: (AAPD reference manual 2002–2003)

<i>Caries risk indicators</i>	<i>Low risk</i>	<i>Moderate risk</i>	<i>High risk</i>
Clinical conditions	<ul style="list-style-type: none"> • No carious teeth in past 24 months • No enamel demineralization • No visible plaque or gingivitis 	<ul style="list-style-type: none"> • Carious teeth in past 24 months • One area of enamel demineralization • Gingivitis 	<ul style="list-style-type: none"> • Carious teeth in past 12 months • More than 1 area of enamel demineralization • Visible plaque on anterior (front) teeth • Radiographic enamel caries • High titers of mutans streptococci • Wearing dental or orthodontic appliances
Environmental characteristics	<ul style="list-style-type: none"> • Optimal systemic and topical fluoride exposure • Consumption of simple sugars or foods strongly associated with caries initiation primarily at meal-times • High caregiver socioeconomic status • Regular use of dental care in an established dental home 	<ul style="list-style-type: none"> • Suboptimal systemic with optimal topical fluoride exposure • Occasional (i.e. 1-2) between meal exposures to simple sugars or foods strongly associated with caries • Midlevel caregiver socioeconomic status (i.e. eligible for school lunch program or SCHIP) • Irregular use of dental services 	<ul style="list-style-type: none"> • Enamel hypoplasia • Suboptimal topical fluoride exposure • Frequent (i.e. 3 or more) between meal exposures to simple sugars or foods strongly associated with caries • Low-level caregiver socioeconomic status (i.e. eligible for Medicaid) • No usual source of dental care • Active caries present in the mother • Children with special health care needs • Conditions impairing saliva composition and flow
General health conditions			

Table 7: AAPD recommended anticipatory guidance for parents*Pregnant women, new mothers or intimate care givers*

- Brush teeth twice a day with fluoridated toothpaste and floss daily
- Spit excess toothpaste after brushing and do not rinse
- Rinse every night with alcohol free OTC fluoride mouth rinse
- Have a dental visit for an exam and restoration of all active decay ASAP
- Educate mother about hormonal changes during pregnancy that can increase a woman's risk for gingivitis

Parents of infants

- Make an appointment for the infant's first dental visit within 6 months of eruption of the first tooth and no later than 12 months of age
- After initial dental visit make future appointments based on the schedule suggested by the dentist, based on the infant's individual needs
- Clean infant's gums with a clean damp cloth or an infant toothbrush with a small head using plain water after each feeding
- Brush infant's teeth as soon as the first tooth erupts usually at the age of 6-10 months twice a day using a soft bristled tooth brush designed for infants
- Give infant nothing to eat or drink after brushing at night, except water
- For infants at increased risk of tooth decay consult a dentist or physician about brushing with fluoridated toothpaste
- Become familiar with the normal appearance of the infant's teeth and gums so problems can be identified if they occur (check once a month)
- Give the infant 6 months or older fluoride supplements but only as recommended by a dentist or physician (based on water fluoride level)
- In case infant has sore gums caused by tooth eruption give infant a clean teething ring, cool spoon or cold wet wash cloth or even rub his gums with a clean finger

Parents of young children

- If the child has not yet been for a dental visit make an appointment for the first dental visit
- After initial dental visit make future appointments based on the schedule suggested by the dentist, based on the infant's individual needs
- For children under age 2 brush the teeth with plain water twice a day
- For children with increased risk of tooth decay consult a dentist or a physician about brushing teeth with a fluoridated toothpaste
- For children ages 2 and above brush twice a day with no more than a pea sized amount of fluoridated toothpaste and make him spit but not rinse
- Young children cannot clean teeth without parental help so they need to be helped as brushing requires fine motor skills (around 7-8 years)
- Become familiar with the normal appearance of the infant's teeth and gums so problems can be identified if they occur (check once a month)
- Give the child fluoride supplements but only as recommended by a dentist or physician based on the level of risk and that of fluoride in the drinking water
- Discuss with a dentist or other qualified health professional the need to apply fluoride topically
- Discuss with a dentist or other qualified health professional the need to apply dental sealants
- In case infant has sore gums caused by tooth eruption give infant a clean teething ring, cool spoon or cold wet wash cloth or even rub his gums with a clean finger

Parents of Infants

Table 7 lists recommendations for pediatricians to give to parents of infants. The pediatrician should educate parents about making an appointment for the infant's first

dental visit within 6 months of eruption of the first tooth and no later than 12 months of age. The dentist then develops a schedule for future appointments based on the infant's individual needs and susceptibility to disease. Visits

might be more frequent for special needs patients. Parents should clean the infant's gums with a clean damp cloth or an infant toothbrush with a small head using plain water after each feeding. They should brush infant's teeth twice a day as soon as the first tooth erupts, usually at the age of 6 to 10 months, using a soft bristled toothbrush designed for infants. An infant should be given nothing to eat or drink after brushing at night, except water, and parents should consult a dentist about brushing with fluoridated toothpaste for an infant who is at increased risk for tooth decay. But parents should be warned not to let the child ingest the toothpaste as this may become an unintentional source of systemic fluoride leading to overdose toxicities. A dentist in a dental home can instill this information in parents; it can go a long way toward good oral health and health practices of the child. Parents should be familiar with the normal appearance of the infant's teeth and gums so they can identify problems if they occur. The dentist can teach the parent through pictures and example, the appearance of the normal versus diseased teeth and gums and should advise parents to assess the infant's oral tissue about once a month. Giving the infant 6 months or older fluoride supplements based on the level of risk and amount of fluoride in the child's drinking water, the physician or dentist may recommend fluoride supplements for the infant who is six months or older. If the infant has sore gums caused by tooth eruption, parents may give infant a clean teething ring, cool spoon, or cold wet washcloth or can even rub infant's gums with a clean finger.

Parents of Young Children

Just like parents of infants, parents of young children should have made the initial dental appointment for their child and should make future appointments based on the schedule the dentist suggested, according to the infant's individual needs and susceptibility to disease. Visits might be more frequent for special needs patients. For children under age 2 the parent should brush their teeth with plain water twice a day after breakfast and before bed, and for those with increased risk of tooth decay, the parent should consult a dentist or a physician about brushing teeth with a small pea sized amount of fluoridated toothpaste. Brushing after breakfast and before bed removes food debris that may remain on teeth after meals and contribute to tooth decay. Parents can brush teeth of children more than 2 years of age twice a day with no more than a pea sized amount of fluoridated toothpaste and make them spit without rinsing as described earlier. Parents should understand that brushing requires good fine motor skill and that young children cannot clean teeth without parental help. After children acquire these fine motor skills, typically at ages of 7 to 8 years (an age at which they can tie their own shoe laces), they can clean their own teeth with parental supervision. Again parents

should be familiar with the normal appearance of the teeth and gums and should perform home oral exams about once a month. The physician should inform parents that they should ask the dentist about the need for fluoride supplements for their child, which the dentist can prescribe based on level of risk and amount of fluoride in the drinking water. In addition, parents of young children can discuss with a dentist the need to apply fluoride topically (like varnishes, gels, foams), which renews the high levels of fluoride in the outer layer of tooth enamel. Topical applications maybe especially effective in children with a high risk of tooth decay such as those who have a history of tooth decay, who are not exposed to fluoridated water, who snack frequently on foods containing sugar, or who have medical problems that decrease their resistance to tooth decay. Also, in a dental home, the parents can discuss with a dentist or other qualified health professional the need to apply dental sealants (thin plastic coatings that are applied to pits and fissures on chewing surfaces of teeth). Sealants create a physical barrier against dental plaque, and this barrier prevents tooth decay. Dental sealants should be applied shortly after the posterior teeth erupt. The pediatrician can also instruct the parent on treatment of sore gums from tooth eruption: give the child a clean teething ring, cool spoon, or cold wet washcloth or rub the gums with a clean finger.

Advantages of Anticipatory Guidance in Specific Dental Conditions

Dental Caries

A transmissible oral infection, dental caries is the most common childhood disease and is five times more common than asthma.² Cariogenic bacteria in the mouth produce acids to breakdown food debris on the teeth. These acids cause tooth mineral loss. Prolonged attack that exceeds the individual's capacity of healing can cause irreversible decay and eventual tooth loss.

More than 6 percent of 1-year-old, 22 percent of 2-year-old, 35 percent of 3-year-old 49 percent of 4-year-old in a Head start program in arizona had clinical tooth decay.³ The third National Health and Nutrition Examination Survey (NHANES), 1988-1994, indicates that 8 percent of 2-year-old in the United States had at least 1 decayed or filled tooth and by age five 40 percent of children did. Children as young as 1 experience untreated tooth decay, and among children ages 6 to 8, 72 percent of American Indian/Alaskan Native, 50 percent Hispanic and 34 percent African-American children experienced untreated tooth decay.³ This vast number with tooth decay clearly indicates the need for preventive action and a need for more aggressive measures in a country like India where access to health care and the dentist-to-population ratio is very low.

Early childhood caries (ECC) may occur in infants or children with prolonged exposure to beverages high in sugar like soda, fruit juices, milk, or formula from a bottle or a cup, prolonged breastfeeding, frequent snacking on foods high in sugar, and pacifiers coated with sweeteners. Volume and composition of saliva and blockage of salivary flow also affects ECC. The younger the age at which decay begins the greater will be the risk of future decay. ECC can affect a lot of teeth and cause severe loss of function and harm to the child's dentition. Good oral hygiene, use of fluorides and dental sealants, good dietary habits, and chemical and physical reduction of plaque can all be achieved with early intervention to prevent ECC.

CARIES PREVENTION THROUGH ANTICIPATORY GUIDANCE

Pregnant Women, New Mothers or Other Intimate Care Givers

The AAPD has recommendations for dietary practices in pregnant or new mothers, infants and children.³ The recommendations suggest that the pediatrician educate the parents about the diet for their children and themselves and that the dentist reinforce these healthy practices. The pediatrician and dentist should advise these women to eat healthy foods and to avoid snacking in between. Healthy meals should include fruits, vegetables, grain products, and dairy products. The foods containing sugar should be eaten at mealtimes only and in limited amounts. This education will help parents develop good oral health practices, which they will pass on to their children.

Physicians should advise pregnant women to choose fruit rather than fruit juice for their recommended daily fruit intake and avoid carbonated beverages during pregnancy and at least for the first 30 months after delivery. Pediatricians should encourage these women to drink fluoridated water, and should inform them about the transmission of bacteria that cause tooth decay from the parent to child and that parents should not share utensils or clean the pacifier or bottle with saliva.

Parents of Infants

The pediatrician should advise mothers to breastfeed the infant for approximately the first 6 to 12 months of life.³ To prevent the transmission of bacteria that cause tooth decay via saliva from mother to child, parents should not share utensils with the child, test the temperature of the bottle with the mouth, or clean a pacifier or bottle nipple with saliva, practices many parents adopt that are not hygienic. The infant should never be put to sleep with a bottle or sippy cup in the mouth, and never allowed frequent or prolonged feeds with beverages high in sugar. These practices are the primary cause of early tooth decay

because parents use them to pacify and to induce sleep in the infant. Pediatricians should tell parents to hold infant while feeding and never to prop the bottle using pillows or other objects to hold the bottle. This propping can injure the unattended infant and prolonged propping and feeding can cause ECC. Some parents also add cereal to a bottle of the infant but pediatricians and dentists should discourage this practice because it will cause sugary foods to pool around teeth increasing the risk for decay. Parents can introduce a small cup when the infant can sit up without support, and the infant should be weaned from the bottle when he starts to eat more solid foods and made to drink from a cup. Parents should not introduce juice into an infant's diet before age 6 months and limit it to 4-6 oz per day. Infants 6 months and older should receive age-appropriate healthy foods as recommended by their pediatrician and avoid snacking between meals. Foods containing sugar should be served to infants at mealtimes only and in limited amounts.³ Pediatricians should have the knowledge or be able to do the required referral for good nutrition and dietary counseling to support oral and general health of the child (Table 8).

Parents of Young Children

The pediatrician should reiterate the following guidelines for young children. To avoid transmission of bacteria that cause tooth decay from parent via saliva to child, parents should not share utensils or clean a pacifier or bottle nipple with saliva. Parents should encourage a child to drink from a cup and to wean them from the bottle at 12-14 months and should not put a child to sleep with a bottle or sippy cup or allow frequent or prolonged feeds for reasons mentioned earlier. Parents should provide age appropriate healthy planned foods and prohibit snacking in between meals. A good healthy meal should contain fruits, vegetables, grains and dairy products. Child should eat fruit rather than drink fruit juice and be served the juice in a cup limiting it to 4 to 6 oz per day. Beverages between meals should be fluoridated water and milk rather than juices and sodas.

Fluorides

The primary factor in reducing the prevalence of cavities among the children in the United States has been the widespread availability of fluoride. According to the CDC, frequent exposure to small amounts of fluoride each day is the best way to reduce the risk of developing tooth decay.⁸ Systemic fluorides only help during the tooth-forming years (ages 6 months–19 years) they enhance resistance to later acid demineralization. They can be delivered in the form of fluoridated water or fluoride supplements available as tablets, drops, or liquids and reach the child's teeth through the digestive and circulatory systems. Fluoridated

Table 8: AAPD recommended anticipatory guidance for parents on good nutrition*Pregnant women, new mothers or intimate care givers*

- Eat healthy foods during planned meals and snacks and avoid snacking in between
- Include fruits, vegetables, grains and dairy products
- Foods containing sugar should be eaten at mealtimes only and in limited amounts
- Choose fruit rather than fruit juice for recommended daily fruit intake
- Avoid carbonated beverages during pregnancy and at least for the first 30 months after delivery
- Drinking of fluoridated water
- Once infant is born avoid transmission of bacteria that cause tooth decay from the parent, like avoid sharing utensils or cleaning pacifier or bottle with saliva

Parents of infants

- Breastfeed the infant for approximately the first 6 months of life can be continued for 12 months
- Prevent transmission of bacteria that cause tooth decay via saliva, avoid sharing utensils, testing the temperature of the bottle with the mouth or cleaning a pacifier or bottle nipple with saliva
- Do not put infant to sleep with bottle or sippy cup or allow frequent or prolonged feeds with beverages high in sugar
- Hold infant while feeding, never prop the bottle using pillows or other objects to hold the bottle
- Never add cereal to a bottle this will cause sugary foods to pool around teeth
- Introduce a small cup when the infant can sit up without support
- Wean the infant from the bottle when he starts to eat more solid foods and drink from a cup
- Do not introduce juice into an infant's diet before age 6 months and limit to 4-6 oz per day
- For infants 6 months and older, serve age appropriate healthy foods and avoid snacking between meals
- Serve foods containing sugar at mealtimes only and limit amount

Parents of young children

- To avoid transmission of bacteria that cause tooth decay from parent via saliva to child avoid sharing utensils, or cleaning a pacifier or bottle nipple with saliva
- Continue to encourage a child to drink from a cup wean from bottle at 12-14 months
- Do not put a child to sleep with a bottle or sippy cup or allow frequent or prolonged feeds
- Allow age appropriate healthy planned foods and avoid snacking in between
- Serve fruits, vegetables, grains and dairy products
- Encourage child to eat fruit rather than drink fruit juice
- Serve the child juice in a cup and limit to 4-6 oz per day
- If child drinks beverages between meals encourage drinking water and milk rather than juices and sodas
- Drink fluoridated water

water is the best way to get systemic fluorides to a child. Fluoride supplements are recommended only when a child's ingestion of fluoride is less than optimal. Table 9 shows the recommended doses for fluoride supplements based on age of child and level of fluoride in the drinking water.⁹ Early referral to a dentist in a dental home can address fluoride issues. The dentist will know the community, and the fluoride content in the water in the community and will be able to prescribe the ideal dosage for the child if necessary.⁵ Topical fluorides are most important in the prevention of tooth decay because they reach teeth directly and are more effective than the small doses in foods, water and fluoridated toothpastes. In a child's

dental home the dentist would know the child and the family and this beneficial relationship would help the dentist treat the individual needs of the child and would also improve compliance in both the parents and the child. The dentist can also professionally apply topical fluorides like varnishes, gels, or foams. These are especially effective in children who are at high risk of dental caries due to lack of fluoridated water, who have a history of caries, who snack frequently on high-sugar foods or have a medical condition. The dentist in a dental home would know all this due to regular appointments, and knowledge of the general health of the family. Pit and fissure sealants are also advantageous in caries prevention especially in

Table 9: Fluoride supplementation guidelines*Fluoride ion level in drinking water in ppm #*

AGE	< 0.3 ppm	0.3-0.6 ppm	> 0.6 ppm
Newborn – 6 months	None	None	None
6 months – 3 years	0.25 mg/day*	None	None
3–6 years	0.50 mg/day	0.25 mg/day	None
6–16 years	1.0 mg/day	0.50 mg/day	None

newly erupted primary and permanent molars with deep pits and fissures, and can be professionally applied by the dentist.¹⁰

ANOMALIES IN THE NUMBER OF TEETH

Many tooth-number anomalies, if recognized early, can help the dentist diagnose more serious general health problems. These anomalies can be markers of certain congenital problems and syndromes and maybe unrecognized in a medical exam. For example hyperdontia (more than the normal number of teeth) indicated by delayed tooth loss in a radiographic and clinical exam. Extra teeth need to be identified and removed early to facilitate eruption of the underlying normal teeth. Hypodontia (less than the normal number of teeth) or anodontia (the complete absence of teeth) are indicators of syndromes like ectodermal dysplasia, which affects a lot of other systems as well. In these cases, the pediatrician and the dentist in the dental home can work as a team to care for these patients.

Anomalies in the Development of Teeth

Hypoplasia, hypocalcification, fluorosis, amelogenesis, and dentinogenesis imperfecta appear as abnormal whitish-to-gray or even brownish discolorations of teeth. The tooth surfaces appear rough and tend to retain more plaque. Teeth that have not developed normally also tend to break or chip easily and are more susceptible to carious breakdown. These conditions need early dental treatment to avoid further loss of tooth structure, and anticipatory guidance can help parents get these children timely dental treatment.

Soft Tissue Conditions

Many soft tissue conditions need early identification and treatment and include viral, bacterial and fungal infections, some of which could be indications of more serious health conditions. These soft tissue conditions include primary herpetic stomatitis, and candidiases, which can be an indication of HIV infection for example. Congenital

cysts and tumors should be excised and treated early, but eruption cysts maybe due to newly erupting teeth that do not need treatment usually but need to be observed. Other conditions like mucocoeles, which are caused by injury to minor salivary glands and result in mucous retention in oral tissues, are typically on the lower lip, and may need early excision. Other lesions that are benign but may need excision include fibromas and papillomas; they can occur anywhere in the mouth. Ankyloglossia also known as tongue tie, is characterized by an abnormally short lingual frenum. If it interferes with speech, then it may require frenectomy as early as possible so that speech problems don't become permanent. Ulcers sometimes occur in young children, due to trauma from a sharp tooth, for example, or could be due to infections, systemic deficiencies, or immune deficiencies. If these conditions remain undetected they may result in bigger problems. Regularly scheduled dental visits in a dental home would allow the dentist to recognize and to treat these problems before they become serious health issues. This can best be accomplished if the pediatrician and the dentists work as a team with a common goal of improving the oral and, in turn, the general health of the child.

Habits

Thumb or digit sucking is a natural reflex for infants. This non-nutritive sucking provides the infant with emotional benefits. Many parents allow a pacifier, and a dentist or a pediatrician can instruct parents in its appropriate use. Until the age of 3, non-nutritive sucking does not cause dental problems, but beyond that it can lead to misalignment of primary teeth. It can cause anterior open bites, movement of the upper front teeth (incisors), and constriction of the maxilla. All of these problems resolve if the sucking habit is discontinued before the permanent teeth erupt. Anticipatory guidance can help parents avoid or curtail this habit in their children. Interventions include talking with the child, using reminder therapy, rewarding the child (positive reinforcement), or, if needed, physically interrupting the habit.

Injuries

Infants and young children commonly tend to injure themselves around the head, face and mouth. Injuries to primary teeth are common in children 18 to 30 months of age because they are still unsteady on their feet.³ These injuries could also be a result of child abuse and neglect.

Parents need to closely supervise infants when they are on chairs, furniture, or any high areas from where they are likely to fall and injure themselves Table 10. Locking doors and using safety gates at the top and bottom of stairs are beneficial with an infant in the house. Pediatricians should advise parents that infants and children be placed in appropriate child safety seats in a motor vehicle and

Table 10: AAPD recommended anticipatory guidance for parents on injury prevention

- Closely supervise infants on furniture, chairs or any high areas
- Lock doors and use safety gates at the top and bottom of stairs
- Place infants and children in appropriate child safety seats in a motor vehicle

Supervise children in playgrounds make sure they play on developmentally appropriate equipment

- Avoid use of infant walkers
- Make children wear helmets when riding on bicycles or tri-cycles
- Wait until children have developed basic motor skills before allowing them to participate in organized sports
- Do not place infant in a shopping cart, instead use stroller or front pack or backpack
- Provide infant's caregiver with a dentist's emergency phone contact and ensure that they are familiar with how to handle oral health emergencies.

not place an infant in a shopping cart, but in a stroller or frontpack or backpack. Parents should not put infants in infant walkers. All of this advice should be a part of follow-up visits, given by pediatricians or dentists, based on the age and activities of the child. Interview questions about different stages in the child's development can help the pediatrician to determine which practices the parents are following and to encourage the parents to institute new practices if needed. Children need parental supervision on playgrounds and should play on developmentally appropriate equipment.³ Children should wear helmets when riding bicycles or tricycles. Before children participate in organized sports, they need to have acquired basic motor skills, which they develop at about 7 to 8 years of age. It is important to provide the infant's or child's parents with a dentist's emergency phone number and ensure that they are familiar with how to handle oral health emergencies. Trauma in children could also be from abuse or neglect. Health professionals must report suspected child abuse or neglect.

Management of Oral Injuries

Pediatricians and dentists should educate parents in advance on the management of children with injuries. They need to know how critical the time is between injury and getting care for the child, how any delay could result in damage that could become permanent. In case of a tooth avulsion, the parents should be informed that they need to find the tooth, hold it by the crown only, rinse it under cold water, and not to scrub it. The tooth needs to be reinserted in the socket making sure it is placed facing

the right way, or, if that is not possible the tooth should be put in cold milk or cold water, and the child should see the dentist immediately. A dental home can help parents in dental emergencies get immediate care for their child and thereby avoid problems like tooth loss and disfigurement.

Children with Special Health Care Needs

Children with special needs are another important group that deserves mention in this chapter. Infants and children with special health care needs maybe at increased risk for developing oral conditions like delayed tooth eruption, malocclusion, dental anomalies, trauma, infections, and soft-tissue enlargements (gingival enlargements). All of these conditions are attributed to several congenital syndromes, medications, or inherent immune deficiencies and include Down's syndrome, Treacher-Collins syndrome, and ectodermal dysplasia. Several medications cause gingival enlargements; for example, dilantin and phenobarbital, which are prescribed for epilepsy, can cause gingival hyperplasia. It is very important for a general health professional to be aware of these conditions: children with these conditions may need dental referrals on a regular basis. Like all children, these children should have their first visit within 6 months of eruption of the first tooth or at 12 months of age. However, future visits may have to be more frequent, maybe at 2 to 3 month intervals. Dental treatments may require additional time to accommodate the child's condition, medications, behavior, and complexity of care. Most important, these children should receive oral health care from those who have experience with this population.

DISCUSSION

India with its population of 1027 million (2001 census), has 72 percent of the population living in a rural setting. The rural health infrastructure consists of subcenters (SCs), primary health centers (PHCs), and community health centers (CHCs). Although the country produces 7000 dentists per annum the dentist-to-population ratio is 1:30,000. There are no dentists or dental surgeons posted at the CHC and PHC levels. Therefore it is very important for the family physician and the pediatrician to be trained to include oral health care as part of the regular health check ups since they are the only health care professionals most of the population has contact with. Physicians must receive adequate resources and information to identify dental risk behavior and should educate parents and caregivers and give necessary referrals for dental treatment.

Dental diseases have been increasing both in prevalence and severity in India over the past few decades, and an urgent need to halt the rising trend of dental diseases in India has arisen.¹¹ Dental caries is a public health problem

with prevalence as high as 60 to 80 percent in Indian children, and is more common than asthma.¹³ Also, about 30 percent of the children suffer from misalignment of teeth and jaws, which interferes with proper functioning of the dento-facial apparatus.¹²

The aforementioned problems are due to the lack of awareness about dental diseases, a missing component of oral health in the present health care setting, inadequate knowledge of general physicians and health care workers about oral hygiene and the prevention of oro-dental problems.¹³ Without question, a health care professional in India should know basic oral health and implement anticipatory guidance for patients.

The incorporation into the Indian health system of the guidelines and recommendations discussed in this chapter will be economically favorable for a developing country like India, where resources are limited and are allocated need wise. It is by far more cost effective to implement prevention and health education than to treat diseases, especially oral diseases, which for a large part are preventable.¹⁵

Since children under the age of 3 years are more likely to see a physician or other health professional earlier and more frequently than a dentist, it is very important that this health professional be knowledgeable about oral health, can recognize oral conditions, and can give necessary referrals. This early coordinated intervention can reduce the prevalence of oral diseases nationwide and can benefit the nation as a whole.

Behavioral Problems in Pediatric Patients

Deepak Gupta, Bhavana Goel

Behavioral problems in pediatric patients are of growing concern in pediatric practice. Pediatrician comes across a gamut of behavioral problems in children in day-to-day practice. Some of them are nonspecific and some of them constitute specific behavioral disorders. Nonspecific problems are few difficulties such as irritability, restlessness, stubbornness, etc. encountered by parents and teachers but they do not amount to syndromal disorder. The unanswered question is how many of these children with nonspecific behavior difficulties go on to develop specific behavioral disorder. In this chapter, the first part will outline the common behavioral problems in the children followed by behavioral disorders in pediatric age group.

COMMON BEHAVIORAL PROBLEMS

Behavioral problems are common in younger children. Western data estimates that 3 to 8 percent of under-fives have moderate to severe behavioral problems¹. The main problems in pediatric patients are attention-seeking and dependency, argumentative relations with other children, overactivity and poor concentration, disobedience and hot tempers. Boys are more likely to be overactive, disobedient and girls are more likely to be fearful and miserable.

These common behavioral problems are issues of concern for parents and many parents consult pediatrician about them. These problems are minor if they are isolated without several associated behavioral difficulties, have been present for less than six months and cause only minimal impairment to the child's life and routines. These isolated behavioral problems respond very well to explanation, self help books or a brief behavioral intervention for a specific problem.

Many times these behavioral problems persist and are associated with other behavioral problems. Problems are more common in the presence of specific language delay or mental retardation,² and adverse social and family

factors such as marital discord, low parental warmth, high criticism and maternal depression. Predictors of persistence are more severe problems, several problems in the same child, low IQ, early onset and adverse social circumstances. Caspi et al (1996) in a landmark study delineated that behavioral phenotypes such as under controlled (impulsive, restless, distractible) and inhibited (shy, fearful, easily upset) types at the age of 3 years can be a risk factor for the future behavioral and psychiatric problems such as drug use, depressive disorder, antisocial behavior.³

Behavioral management principles are the mainstay of treatment for common behavioral problems. Individual counseling of the younger child has not been shown to be effective, and medication should be considered if the problems are persistent and severe enough to be considered as syndromal behavioral disorders. Otherwise medications are seldom required and usually the condition relapses on stopping.

Behavioral management principles state that most behavior is influenced by antecedent events and consequent responses. Altering these may change the frequency or intensity of the behavior. Parents are encouraged to reinforce the behavior they want to see more often and to extinguish unwanted behaviors. For most children positive attention from the parents by smiles, eye contact, hugs and praises is the most effective reinforcement and may be supplemented by stars, small treats and rewards. While behaviorally-based treatments have a high face validity and may seem like common sense, working out such programs can be surprisingly difficult and demanding if inadvertent reinforcement of unwanted behaviors is to be avoided.

BEHAVIORAL DISORDERS

Attention-deficit/hyperactivity disorder (ADHD), conduct disorder (CD), and oppositional defiant disorder (ODD)

are the various behavioral disorders seen in pediatric patients. As a group, these are the most common disorders of childhood and among the most researched areas of childhood psychopathology. There is also increasing recognition that these disorders continue into adulthood.⁴

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

The cardinal features for children with attention-deficit/hyperactivity disorder (ADHD) are excessive motor activity, inattention and impulsiveness.⁵ Compared with their peer group, these children are restless, fidgety, and boisterous when required to be still and quiet. This is true both in structured situations, such as the classroom, and in unstructured situations, such as the playground. They have difficulty attending to instructions in academic and social situations. They tend to look away when spoken to, require frequent repetition of directions or appear unable to comprehend the nuances of an instruction. At school, their work is characterized by careless errors, poor organization and forgetfulness. They lose things such as books, notes and assignments that are crucial to school work but they also lose possessions that are of obvious personal value. They are typically last to start a designated activity (often because they cannot find the necessary materials, forget to gather them together or have been daydreaming) and last to finish (because of staring off into space, failing to concentrate and being distracted). They shout out their replies, interrupt others and are reckless and accident-prone. On the other hand, they may not speak when they are supposed to.

The characteristics of ADHD are variable both within and among individual children.⁵ It is rare to find a person who exhibits every characteristic of hyperactivity to a comparable extent. It has been seen that children with ADHD can have varied symptoms which are context-dependent varying with the demands of the situation in school and at home. Parents frequently comment that it is the marked variability day-to-day, hour-by-hour and minute-by-minute that is the most salient feature of these children. The profile of these children changes with age and development. Hyperactivity remains the prominent feature in preschool years with inattention becoming more salient once child confronts the demands of the classroom. By the time children reach adolescence, the motor activity seems to diminish, and inattention and impulsiveness become most impairing and are particularly noticeable in social situations.

Children with ADHD experience serious social, academic and psychological impairment at every stage of development. In comparison to their normally developing peers, children with ADHD have poor school performance and are more likely to have a diagnosis of a learning disability.⁶ Poor school performance results in low self-esteem, peer rejection and emotional problems

which can lead to school dropout, risk of delinquency and substance abuse. They are rejected by peers and adults and treated in a controlling and negative fashion by them. Their parents experience considerable stress and feelings of incompetence as parents which can cause frustration, emotional problems and depression in them. Children with ADHD are more likely than their unaffected peers to live in families that are disrupted by poverty, characterized by material discord and parental psychopathology and to have siblings who are at risk for the development of psychopathology.⁵

Various subtypes of ADHD have been distinguished, based on phenomenology, pervasiveness of symptoms, response to treatment and patterns of comorbidity but most of them remain less well established and speculative except the subtypes based on symptom profile. A distinction between hyperactive-impulsive, inattentive and combined hyperactive-impulsive and inattentive subtypes is made,⁷ although the true significance of this distinction is unknown. The inattentive and combined subtypes are about equally prevalent among school-age children and are more common than the hyperactive-impulsive subtype which is more common in very young children. Many children with the hyperactive-impulsive subtype have combined subtype on follow-up.

Many children with ADHD meet the criteria for another psychiatric disorder. In general, ODD is observed in 35 to 50 percent of cases, conduct disorder in 25 percent, depressive disorder in 15 to 20 percent and anxiety disorder in 20 to 25 percent. Learning disability occurs in 15 to 40 percent of children, particularly among those with inattentive symptoms, and language impairment in about 15 to 75 percent of children. In fact over 50 percent of children with ADHD meet criteria for two comorbid conditions.^{5,8}

Originally, ADHD was thought to be a transient phenomenon because of the tendency for symptoms, especially restlessness, to diminish as children grow and reach adolescence. Inattention and impulsiveness are more persistent manifestations and it is now clear that the disorder persists into adolescence in half or more of affected persons, and into adulthood in half or more of adolescent cases.⁶ Poor outcome in adolescence and young adulthood is more likely when the affected child experiences stressful life circumstances, such as those that are commonly associated with poverty, overcrowding, negative expressed emotion in the parent-child relationship, and parental psychopathology. Prognosis is also worse when the ADHD symptoms are severe, and predominantly hyperactive-impulsive in nature and when the child exhibits early conduct, language or learning disorder. Nevertheless, the poor outcome of children with ADHD is not simply a function of these early associated impairments; ADHD increases the risk of a poor outcome, even when due allowance is made for the associated risk factors.^{9,10}

The prevalence of ADHD depends to a great extent on various factors such as diagnostic measures used, sampling method, number of informants used, etc. Overall the prevalence varies from 2 to 10 percent in school-age children with boys having higher rates than girls (2-4:1). In general prevalence declines with age, but follow-up studies support that ADHD persists into adolescence and adulthood.⁶

Attention-deficit/hyperactivity disorder (ADHD) is an etiologically heterogeneous disorder that can be caused by a range of biological, psychological and social conditions that act individually or together to increase the risk of ADHD. Much of the available evidence points to the importance of abnormal higher order cognitive functions caused by dysfunction in catecholamine (dopamine, adrenaline and noradrenaline) metabolism and neurotransmission in the prefrontal cortex and associated subcortical structures. Deficits in these processes are common among children with ADHD and are thought to be the proximal cause of their poorly regulated everyday behavior and impaired performance on laboratory tasks.¹¹ Relatives of individuals with ADHD having increased risk for ADHD, a markedly higher concordance of ADHD for monozygotic (79%) than dizygotic (32%) twins, biological parents of ADHD individuals more likely to exhibit ADHD or related disorders than are adoptive parents offer strong evidence of genetic susceptibility to ADHD.⁵ It is now established that certain alleles of the genes coding for the dopamine D4 receptor (7-repeat-allele) and the dopamine transporter (10-repeat-allele) occur more frequently in children with ADHD than in healthy controls.¹²

A range of psychological and neurobiological risk factors are associated with ADHD, including maternal stress during pregnancy, poor quality or disrupted early care giving as may be seen in children in institutions foster care, fetal exposure resulting from the mother's use of alcohol, drugs or cigarettes, the adverse effects of perinatal obstetrical complications or prematurity, traumatic brain injury, iron deficiency and exposure to environmental toxins such as zinc or lead. These risk factors probably interact among themselves and with genetic risks, making the specific role of any single factor difficult to assess accurately the etiology of ADHD.^{4,5}

To diagnose ADHD, the clinician should obtain information from the child's parents, the child and the child's classroom teacher. Behavior rating scales provide a valuable, simple and inexpensive means to collect descriptions of child behavior from various informants. During the assessment, the presence of a concurrent disorder and the relationship of the symptoms of a comorbid disorder and ADHD should be assessed. Children with ADHD are able to suppress their inattention, restlessness and impulsiveness to a great extent in novel and highly structured situations, such as those afforded by the typical visit to the clinic. Nevertheless, the interview

of the child may be useful for identifying comorbid disorders, assessing the relationship of symptoms to anxiety or academic demands, monitoring treatment, and establishing the report that is required to sustain a prolonged intervention. Because many children meet ADHD criteria almost exclusively on the basis of behavioral difficulties within the school context, it is essential to assess the presence of learning difficulties and language problems, the nature of the educational experience and the quantity of the child's relationships with peers and teachers. Intelligence test (IQ) and educational assessment to rule out mental retardation and learning difficulties are required whenever the child has poor school performance and difficulties in reading, writing and arithmetic. As there is no diagnostic test for ADHD, specific blood test, EEG and neuroimaging techniques are reserved for individual cases having high suspicion of organicity, dysmorphic features, and regression in milestones and should not be done on a regular basis. Recently there has been an alteration in the diagnostic criteria for ADHD. According to new guidelines issued by the American Academy of Pediatrics (AAP, November 2011) the age range for the diagnosis and treatment of attention-deficit hyperactivity disorder (ADHD) has been expanded to children as young as 4 and as old as 18 in contrast to original age range of 6 to 12 years.

Currently the accepted approach to treatment involves long-term multimodal intervention in which various pharmacological and psychological treatments and combinations of treatment are used together with a supportive management strategy. The mainstay of treatment is stimulant medication with psychological therapy involving family. Special diet (Feingold diet, elimination diet, reduce sugar intake), dietary supplements, Omega-3 fatty acids, and electroencephalographic (EEG) neuro-feedback are also used as an alternative to medication with promising results in certain children but more adequate scientific data is required.

Psychostimulants including methylphenidate (short term and sustained release available in India), dexamphetamine and pemoline, have shown to be effective in the treatment of ADHD. Numerous placebo-controlled randomized control trials confirm the substantial short-term benefits of stimulants.¹³ Although stimulants have proved effective, they have their limitations. They are thought by many to be prescribed too frequently and inappropriately and to be a public health risk in their own right because of their potential for undetected long term adverse events, for abuse and for the way that they can distract from 'genuine' treatments. Medication is not an acceptable treatment option for many children and families. Families are concerned about the biological or ethical implications of treating young children with drugs or about the potential for unknown long term risks of treatments. Lack of adherence limits the effectiveness of medication, as it does with

all medical treatments. Even though a beneficial impact of behavior, as rated by their teachers, may occur in about 70 percent of treated children, treatment normalizes the behavior of only about half of children and many disabilities remain. One of the most significant limitations of stimulant medication is the lack of evidence of its efficiency over prolonged periods of treatment.

Other drugs used in the management of ADHD and comorbid disorders include antidepressants, clonidine and its analogues, selegiline, newer atypical neuroleptics, and atomoxetine, a novel, nonstimulant therapy that has potential to fulfill some unmet treatment needs. Atomoxetine is a highly selective noradrenaline reuptake inhibitor that has been studied for use in the treatment of attention deficit/hyperactivity disorder (ADHD). Recent data from clinical trials show it to be well tolerated and effective in the treatment of ADHD in children, adolescents, and adults. Improvements are seen not only in core symptoms of ADHD, but also in broader social and family functioning and self esteem. Once-daily dosing of atomoxetine has been shown to be effective in providing continuous symptom relief. Atomoxetine does not appear to have abuse potential and is associated with a benign side effect profile. The development of atomoxetine represents an important advance in the pharmacological management of ADHD.¹⁴

Various psychological therapies have been used for ADHD, either as an alternative to medication or as a method of augmenting the effects of medication. Behavior parent training is the most commonly prescribed psychological intervention for ADHD predicated on the observation that parents of children with ADHD use overly controlling and inefficient parenting strategies and that adversity in the parent-child relationship is predictive of poor outcome.¹⁰ Parent-training programs (Table 1) use instruction, modeling and role-playing to teach parents to reinforce positive behavior, decrease the use of punitive strategies, and manage defiant, stubborn and inappropriate behavior effectively which improves the parents' child management skills, enhance their self-confidence, reduce family stress and mitigate oppositional behavior. However, parent training does not reduce the core symptoms of ADHD as effectively as does stimulant medication, nor does it appear to enhance the effectiveness of stimulants. Benefits tend not to persist beyond the period of treatment. Cognitive behavior therapy attempts to enhance self-control by teaching children self-instruction strategies. Social skills training targets the child's problems with peers and adults, typically in a group setting.

Overall, the evidence strongly supports the use of stimulant medications for treating the core symptoms of children with ADHD and, to a lesser degree, for improving functioning. Behavior therapy alone has only limited effect on symptoms or functioning of children with ADHD,

Table 1: Management tips for parents for children with ADHD

- *Basic techniques for attention enhancement*
 - Call the child by name
 - Make an eye contact with the child before talking to him/her
 - Use slight touch at times to gain child's attention
 - Keep the message short and clear
 - Be very crisp while talking to the child
 - Give single command at a time
 - Avoid detailed explanations
 - State the command positively
 - If possible give the child an option
- *Basic management for increasing organizational skills*
 - Encourage use of checklist
 - Encourage use of stopwatch to time self for completion of work
 - Making a time table
 - Organize everyday items. Have a place for everything, and keep everything in its place. This includes clothing, backpacks, and toys.
 - Use homework and notebook organizers. Use organizers for school material and supplies. Stress to your child the importance of writing down assignments and bringing home the necessary books.
- *Basic management for increasing compliance of instructions*
 - Set clear rules/discipline for home
 - Have prescribed consequences of misbehavior
 - Postpone the child's desire gradually starting from 2 minutes to 10 minutes to 20 minutes
 - Be clear and consistent. Children with ADHD need consistent rules they can understand and follow.
 - Give praise or rewards when rules are followed. Children with ADHD often receive and expect criticism. Look for good behavior, and praise it.
- *Basic management for channelizing energy positively*
 - Give frequent study breaks
 - Have a zero tolerance policy for hitting, pushing and yelling in your house or yard.
 - Encourage the child to participate in more sport activities (physical).

although combining behavior therapy with medication seems to improve functioning and may decrease the amount of (stimulant) medication needed.¹⁵

Conduct Disorders

Unlike most disorders, conduct disorders (CDs) are entirely defined in terms of the individual's relationship with other people and society. There is a persistent pattern of antisocial behavior whereby the individual repeatedly breaks social rules and carries out aggressive acts that disturb other people. This persistent tendency typically starts young and carries on until at least middle age. Thus a substantial proportion of children and adolescents with conduct disorder grow up to be antisocial adults, leading impoverished and destructive lifestyles; a significant minority will develop antisocial personality disorder

Table 2: Clinical features of conduct disorders
(Modified from ICD-10 DCR)¹⁷

<i>Conduct disorder (CD)</i>	<i>Oppositional defiant disorder (ODD)</i>
<ul style="list-style-type: none"> • Aggression to people and animals • Destruction to property • Deceitfulness or theft • Serious violation of rules 	<ul style="list-style-type: none"> • Unusually frequent or severe temper tantrums • Often argues with adults/actively refuses adults requests or defies rules • Often, apparently deliberately does things that annoy others • Often blames others for their own mistakes/misbehavior • Often angry/resentful/touchy • Often spiteful/vindictive

(psychopath). The personal impact and cost to society is high, since many domains of living are affected, many professionals and agencies get involved in managing the sequelae.¹⁶

Conduct disorders (CDs) comprise (Table 2) oppositional defiant disorder (ODD) which mainly affects younger children, and conduct disorder (CD) which affects older children and teenagers.¹⁷ In some children ODD is followed by features suggestive of CD. Approximately 90 percent of children with CD would also meet the criteria for ODD⁴. It is doubtful whether ODD differs substantially from CD in older children in any associated characteristics, and the value of designating it as a separate disorder is arguable. They are both variants of antisocial behavior although they differ on the intensity and severity (Table 2), so many clinicians call both as conduct disorders (CDs) and henceforth in the following text both will be discussed as CDs.

Although the Indian data is lacking, as per western data the rates for CD have been estimated to as low as 0.9 percent for school-age children but as high as 8.7 percent in adolescents. The overall prevalence of ODD varies across studies from 4 to 15 percent.⁴ Available evidence suggests that the juvenile crimes have risen and specific studies of CDs across cohorts also suggest a rise over the last 40 years. CD is common in boys at all ages, but the ratio of boys to girls depends on the type. In childhood, for oppositionality, boys outnumber girls by around 4:1. In adolescence the ratio narrows to around 2:1.

Major differences are found between early and adolescent onset CD. Those with an early onset display defiant and aggressive behavior before the age of 8, but it typically begins around 3 years of age. They go on to increasingly antisocial behaviors as they grow older. However, not all young children with this early onset pattern progress to more severe difficulties later in childhood. Only about half persist; the remainder improves. Compared to the adolescent onset group, the early onset children at three years show a more difficult temperament (restlessness,

inattention, negativity, irritability, etc.). At school age this group has cognitive, language and motor deficit, reading difficulties, adverse family contexts and poor parenting. By 18 years they have fewer friends and feel socially alienated, victimized, and are callous and suspicious. They continue behaving antisocially as adults. This pattern of antisocial behavior has been described as early onset-lifetime persistent.

Common by about 3 to 1 are the adolescent onset group who have not shown significant antisocial behavior earlier in their lives. Moreover by their early twenties they have reduced their level of antisocial behavior to less than half the level of the early onset groups. This group has been described as adolescence-limited, although they may not completely stop in adulthood and further studies will answer this question. The overall rate of arrests and convictions is somewhat lower than the childhood onset type, there are more girls (about 2:1 instead of 4:1 for childhood onset). Their behavior tends to be less aggressive and violent, less impulsive, they have fewer cognitive and neuropsychological deficits, more mood symptoms, tend to come from less dysfunctional family environments, and tend to be more adaptive socially. Crucially, the adolescent onset groups are more likely to stop offending in early adulthood than the early onset groups. There is only a small group of individuals who commence persistent antisocial activity in adulthood, less than 10 percent of the total.¹⁶

The outlook in children with CDs is determined by the frequency and intensity of antisocial behaviors, the variety of types, the number of settings in which they occur, and their persistence. The main settings where antisocial behavior in children and adolescents is manifested are home, school, and in public. There are many children who are perceived to be mildly or moderately antisocial at home but well behaved at school, and vice versa. However, for more severe antisocial behavior, there are usually manifestations both at home and at school. Concerns about antisocial behavior in public occur more commonly in adolescents and often lead to legal problems.

The duration of symptoms is another important consideration. Many children go through phases of becoming more defiant and argumentative for a few weeks or months. Sometimes this may be a reaction to a change in circumstances such as setting into a new school, or losing a friend or loved one. Only when difficult behavior has been present for 6 months or more, then it is likely to indicate substantial problems.

Making a diagnosis of conduct disorder is usually straightforward since parents readily volunteer the symptoms, although it is essential to obtain an independent report from school so as not to overlook behavior in that context. Sometimes the diagnosis may be inappropriate since antisocial behavior may arise

as a part of other disorders such as autism or mania, or may not be severe enough to warrant a diagnosis. More commonly the diagnosis is correct but comorbid conditions such as mood disorders are missed which are more common in adolescent onset group. Observation of parent-child interaction is invaluable which can be done when the family is seen together at the initial stage of the consultation. Individual session with the child is important as it may reveal some evasiveness about the difficult behavior, home environment and mood symptoms but appreciation of the child's strengths and demonstration of understanding by the clinician can go a long way in building trust. Physical examination should be carried out, looking for dysmorphic features, usually most evident in the face and hands. No medical tests are usually necessary, although chromosomal examination should be undertaken if dysmorphic features are found with EEG and neuroimaging techniques undertaken if there is a history of head injury, loss of consciousness or epilepsy. Cognitive assessment with an IQ test and assessment for learning difficulties is desirable if academic performance is sub-average.

As for any psychiatric disorders, both genetic and environmental risk factors contribute (Table 3). Whilst in the last 20 years genetic factors and nonshared (unique) environment have become recognized as major determinants for most disorders, for conduct disorder

family style, particularly parenting is much more of a major cause, together with temperament factors including hyperactivity and IQ.¹⁶

Protective factors in children who do well despite adverse risk factors have been studied. These so-called 'resilient' children, however, have been shown to have lower levels of risk factors. Protective factors are mostly the opposite end of the spectrum of the same risk factor, thus for example good parenting and high IQ are protective. Nevertheless there are factors which are associated with resilience independent of known adverse influences. These include a good relationship with at least one adult, who does not necessarily have to be the parent; a sense of pride and self-esteem; and skills or competencies.

Engagement of the family is particularly important in treatment for this group of children and families as dropout from treatment is high, at around 30 to 40 percent. Careful assessment of parental functioning is especially important in conduct disorders as it is such a major determinant of the problem, and such as effective and rewarding means of treatment. Parenting interventions may need to go beyond skill development to address more distal factors which prevent change. For example, drug or alcohol abuse in both parent, maternal depression, and a violent relationship with the partner are all common which need to be addressed. There is no evidence that in-patient admissions lead to gains that are maintained after the child is returned to their family, so this costly course of action is not recommended. A multimodal approach is likely to get larger changes.

Proven psychological interventions in CDs include those which singly or in combination address:^{4,16,18,19}

- Parenting skills
- Family functioning
- Child interpersonal skills
- Difficulties at school
- Peer group influences

Programs designed to improve parenting skills and the quality of the parent-child relationship have been found in randomized controlled trials to be effective for children up to about 10 years old.^{16,19} They address the parenting practices identified in search as contributing to conduct problems. Typically, they include 5 elements:

- Promoting play and a positive relationship
- Praise and rewards for sociable behavior
- Clear rules and clear commands
- Consistent and calm consequences for unwanted behavior
- Recognizing the child's day to prevent trouble.

Treatment can be given individually to the parent and child, which enables live feedback in light of the parent's progress and the child's response. Alternatively, group treatments with parents alone have been shown to be equally effective. Trials show that behavioral parenting programmers are

Table 3: Risk factors for conduct disorders (CDs)^{4,16}

Genetic

- Genetic influences – in early onset with comorbid hyperactivity
- XYY karyotype – higher rate of criminal behavior

Child characteristics

- Difficult temperament
- Hyperactivity/ADHD
- Social skill deficits, low self esteem
- Faulty thinking style/distorted cognitive attributional bias
- Physical and sexual abuse
- Low IQs, deficits in executive control functions, autonomic arousal

Family environment

- Coercive parenting styles
- Harsh, erratic discipline
- Lack of warmth, critical/hostile
- Poor supervision
- Marital discord/broken homes

Psychiatric problems in parents

- Depression, drug use, psychoses
- Criminality of father

Environment beyond the family

- Poorly organized unfriendly schools
- Deviant peer influences, rejection by peers
- Alcohol and drug use
- Overcrowding, poor housing, poor neighborhoods

effective in reducing child antisocial behavior in the short term, there is little loss of effect at 1 or 3 years follow up. Parenting skills interventions are chiefly used with younger children, although there is evidence for their successful use with delinquent boys.

Multisystematic therapy¹⁸ and treatment foster care²⁰ aim to change a range of difficulties which impede effective functioning of teenagers with conduct disorder. Multisystematic therapy was developed by Henggeler and colleagues in the USA. The young person's and family's needs are assessed in their own context at home and in their relations with other systems such as school and peers. Following the assessment, often methods of intervention are used to address difficulties and promote strengths. Treatment foster care is another way to improve the quality of encouragement and supervision that teenagers with conduct disorder receive. The young person lives with a foster family specially trained in effective techniques; sometimes it is ordered as an alternative to jail. While the young person is living with the specially trained foster cares, the families of origin are trained in effective methods. Outcome studies following return to the birth family show useful reductions in rates of reoffending.

Most of the programs to improve child interpersonal skills derive from cognitive behavior therapy²¹ which helps young persons to:

- Slow down impulsive responses to challenging situations by stopping and thinking
- Recognize their own level of physiological arousal, and their own emotional state
- Recognize and define problems, develop several alternatives responses and choose the best alternative based on anticipation of consequences
- Reinforce themselves for use of this approach.

Difficulties at school can be divided into learning problems and disruptive behavior. There are proven programmers to deal with specific learning problems. There are several schemes for improving classroom behavior, which vary from those which stress improved communication and those which work on behavioral principles are part of a multimodal package. Many of these schemes have been shown to improve classroom behavior, and some specifically target children with conduct disorder. At the level of the individual teacher with a particularly disruptive child, two or three sessions spent imparting and refining basic behavioral management techniques can lead to substantial improvement in classroom behavior and learning.

A few interventions have aimed to reduce the bad influence of deviant peers. However, a number attempt this through group work with other conduct disordered youths. But outcome studies showed a worsening of antisocial behavior. In modern treatments therefore, either youths are seen individually where an element is to try to steer them away from deviant peers, or the work is in small groups (say 3-5 youths) where the therapist can control the

content of sessions. Some interventions place youths with conduct disorder in groups with well-functioning youths, and this has led to favorable outcomes.

There is no convincing evidence that medication has any specific effects on conduct disorder. Extreme irritability just might be part of a manic illness and so respond to lithium, anticonvulsant or mood stabilizing drugs, but in the absence of other features confirming the diagnosis of a manic illness medication should not be given. Neuroleptics can, unsurprisingly, have a sedative effect and are not infrequently used for challenging behaviors in children and adolescents with mental retardation, but several studies show that if psychological management is better, this usage declines or stops. Where there is comorbid hyperactivity in addition to conduct disorder, several studies attest to a large reduction in antisocial behavior with medication, both at home and at school. However, the impact on long-term outcome is unstudied.

Overall, much is known about the causes of conduct disorder, and there are many effective interventions available. The challenge is to make these universally available, and to deliver them with quality and fidelity so the life changes of the young people improve.

Also there are various sociocultural factors that influence the diagnosis and management of the behavioral disorders. It is important to note that manifestation of them can be very culture specific. However, our most of the diagnosis and management plans are based on western studies done on western populations. This becomes one of the limitations of the treatment processes practiced in India. Further, on one hand western world is often accused of over diagnosis and overmedication of ADHD and behavioral disorders, and on the other side in India, the problem of under diagnosis remains to be a huge concern. This problem is due to various factors like lack of awareness, lack of good culture sensitive assessment tools, limited child and adolescent mental health services, etc. Both of these concerns indicate conducting more Indian research to understand the behavioral disorders in children and also to develop productive therapy modules which are culture specific and hence more beneficiary and cost effective in our Indian scenario.

KEY POINTS

- Behavioral problems are common in children and behavior management principles are effective in their management.
- ADHD and conduct disorders present as challenging behavioral disorders in pediatric age group and have substantial risk for poor outcome in adolescence and adulthood.
- Multimodal treatment including a variety of pharmacological and psychological interventions have been found to provide success over the short term, and

increasingly data indicate that treatment effects can be maintained over more extended period of time.

- Indian studies are needed to understand complexities of behavioral problems and behavioral disorders in pediatric age group and to develop culture specific and cost effective interventions.

Psychosocial Aspects of Chronic Diseases

Roma Kumar

Learning that a child has a life-threatening illness and adjusting to the demands of treatment are amongst the most distressing experiences that a family can face. Although family therapists and psychologists often treat families with seriously ill children, there has been little rigorous family research in this area. Both children and adults with medical illnesses have benefited from twentieth century advances in medicine, and clearly still more advances loom on the horizon of this century. Children who, in the past, might have died or had their physical functioning severely comprised by their illness are now living into adulthood. As more children survive childhood diseases they have a potentially better quality of life than ever before. The leading consequence is that attending to children's physical care also requires attending to their psychological well-being. Mental health professionals have been increasingly sought out by families and physicians to help chronically ill children and their families with illness related problems optimize psychological functioning throughout life.

Illnesses and their treatments change, both within the course of illness and over time. Indeed, in most childhood chronic illnesses, substantial progress has been made in recent decades in treatment and cure. These changes have affected the type of care that families provide, and often the meaning of the illness for the child and family. In childhood diseases, illnesses that were once fatal are now curable. Thus childhood cancer has become more akin to chronic disease (rather than terminal illness) as treatment spans several years and survival becomes a strong possibility for particular illnesses.

Changes in treatment and survival alter the developmental framework for understanding family adjustment. With early onset and treatment lasting many years, childhood chronic disorders affects the family system during its early childrearing years and results in a population of

survivors who are still young children. Specific issues for families at this stage include

- Other infant or preschool children,
- Normal developmental behaviors (high level of activity, fearfulness) accentuated by treatment,
- Discipline of ill preschoolers, and
- Parents balancing childrearing and employment demands.

The long-term impact of surviving an illness that killed peers but that is largely inaccessible to conscious memory is an unknown and interesting question. Furthermore, although children may recall little of the experience, the long-term memory of the child's illness and its legacy in the family is likely to persist.

The concept of "psychological problems" is broad and comprises a large number of possible components. There exists a wide variety of theoretically based instruments intended to tap various aspects of the human psyche. Anxiety and depression are among the most common psychological problems that are discussed and studied in relation with disability.

The proportion of children affected by chronic illness is relatively high, approximately 10 to 12 percent. For these children, there is no available cure and the best that medical care can currently offer is relief from symptoms and the opportunity to participate in normal life as far as possible. Epidemiological work suggests that many of the children experience relatively few restrictions on everyday life, but about 1 to 2 percent of the total population of sick children have more severe conditions.¹

Chronic illness has been defined as, "a disorder with a protracted course that can be fatal or associated with a relatively normal life span despite impaired physical or mental functioning. Such an illness frequently shows a period of acute exacerbations requiring intensive medical

attention.” Chronic illness or disease differs from acute illness in that,¹ it is treatable yet not curable, thus needs management for long periods of time, and therefore,² the responsibility for the management of the illness is shared with and/or transferred to the child and family. Illnesses such as asthma, insulin dependent diabetes mellitus (IDDM), congenital heart disease, juvenile rheumatoid arthritis, sickle cell disease, hemophilia, cystic fibrosis, cancer, and AIDS fit this definition of chronic illness. Although these conditions have distinct biological processes, there are numerous commonalities with respect to the psychosocial impact on the child.

Historically, clinical psychology has focused on pathologies perceived to be within individuals, with intervention geared toward remediation after the onset of psychopathology. More recent developments have modified this orientation to include prevention and increase involvement with individuals whose problems do not necessarily involve psychopathology or in situations in which an orientation that is broader than an intra-individual focus is warranted. In childhood chronic disease, psychological problems can become a primary handicap, although for most of these children diagnosable psychological disturbances are not found. It is not uncommon, however, to see mild-to-moderate levels of distress or psychopathology somewhere within the family system. Psychological distress appears to be related to several variables, including the nature and course of the illness; individual coping resources; family structure and function; and medical, psychosocial, and educational resources. In many medical settings, children with chronic health problems are referred to psychologists because of concomitant cognitive impairments that require assessment and the integration of recommendations with other health care professionals. Although developmental, educational, social and family issues are often explored, the involvement of psychologists in this process has frequently been limited to cognitive assessment or to the management of behavior problems. In terms of assessment, intervention, and research, psychologists' roles with chronically ill children can be expanded.

In this chapter we discuss the issues critical to understanding the psychology of chronic medical illness – definitions and prevalence, models for understanding the interaction of illness and psychological adjustment, psychological risk factors, causes of adjustment problems and psychological disorders as well as strategies of prevention and intervention. Understanding the interaction of the medical illness and psychological factors can form the basis of an intervention plan that can affect the course and outcome of the illness and maximize the well-being of a child with chronic medical illness.

Chronic diseases share the following characteristics:

- They have a biological, psychological or cognitive basis
- They last, or are virtually certain to last, for more than one year
- They are associated with one or more of the following sequel:
 - Limitation of function, activities or social role in comparison with healthy, same-age peers in the areas of physical, cognitive, emotional and social functioning, as well as growth and development
 - Dependency on one or more of the following to compensate for or minimise limitation of function, activities or social role: medications, special diet, medical technology, assistive device, personal assistance
 - A need for medical care or related services, psychological services or educational services over and above the usual for the child's age, or for special ongoing treatments, interventions or accommodations at home or school ²

PSYCHOLOGICAL IMPLICATIONS OF LIVING WITH CHRONIC DISORDERS

- Stress and anxiety
- Depression and low mood
- Fear of dying/ breathless/ exacerbation
- Panic
- Altered body image
- Altered role in family
- Loss of control and independence
- Lifestyle changes
- Alteration of relationships
- Low self-esteem/sense of worthlessness
- Denial
- Anger
- Loss of dignity
- Frustration
- Guilt
- Loss of intimacy
- Irritability and impatience

Expression of emotion is closely linked with dyspnea and some patients may avoid emotion as an adaptive coping mechanism. This may result in patients living in an 'emotional straight jacket', which may then predispose to or compound existing anxiety and depression.

Impaired physical and social dimensions of daily living often result in a sedentary lifestyle with progressive dyspnea and fatigue. This in turn leads to social isolation and an inability to participate in many activities of daily living.

PSYCHOLOGICAL RISK FACTORS RELATED TO ILLNESS

The coping ability and adjustment of the chronically ill child or adolescent depend on multiple factors. These include risk factors related to the illness itself and resistance factors related to the individual. Although there is no one-to-one relationship between any particular risk factor and a particular outcome, the areas of influence include:

- *The degree to which the illness impairs functioning:* Functional disability seems to increase the risk of psychological problems, but the relationship is complicated by other factors. For example, it has been suggested that visibility of illness may contribute to improved psychological functioning because the inability to hide or deny the condition may compel the child to adjust and accept his status;
- *Involvement of the brain:* Behavior, social and cognitive problems have been consistently associated with conditions or treatments affecting the brain. In some instances, insults to the brain, as when a stroke or tumor occurs, can lead to impairments in cognitive functioning that can cause learning problems or social skills deficits;
- *The nature of the illness:* the severity and the course of the illness, and the direct threat to life influence psychological concerns and outcome. For example, cystic fibrosis impairs lung functioning and decreases later life expectancy. Thus, fear of death may increase over time in concert with the change in illness status. For a child with cancer, in spite of a possible 70 to 90 percent rate of remission for some forms of cancer, the terror of death at diagnosis is more likely to occur than for someone diagnosed with IDDM;
- *The type of medical procedures and hospital/non-hospital required experience:* Direct interventions—painful or benign—and where they occur vary widely. Sickle cell disease may require ongoing lifestyle changes with intermittent hospital admission for painful crises. This illness biography impacts a child differently than a lifetime routine of self-administered insulin injections by a child with IDDM or the surgery and concentrated 14-month treatment for a child with bone cancer;
- *The interference with nonillness related aspects of life:* An illness can easily spill over into or consume other areas of life. A child with acute lymphocytic leukemia may need chemotherapy and related treatment for three years. This treatment necessitates sporadic school absence that is likely to affect social and academic skills development. These academic and social risks are different than those for the child with juvenile arthritis, for example, who must have a modified school athletic program;
- *Family functioning:* Both the way the family functions and the effect of the illness on the family influence the child. Parents, siblings, grandparents, and extended family members are prone to particular expected reactions to illness that in turn impact the child. Parents' emotional well-being and style of coping directly affect the child, either due to the child's modeling of parents' reactions, or because the parents' functioning changes the family environment. Marital stress and family functioning can be either helped or hurt when a child has a chronic illness, but illness alone does not automatically cause long lasting family trauma. The consensus is that a child does best when a family is cohesive, flexible, and supportive, the mother is coping well, and communication is open and clear;
- *The individual characteristics and internal resources of the child:* Preillness personality, functioning, and coping ability interact with the illness related situation to affect the level of distress for the child. Anxiety and learning disorders, attention-deficit/hyperactivity disorder, etc. exist in the general population as does poor family functioning, abuse and neglect—all of which can be components in the child's life irrespective of, but affecting, the illness picture. Unfortunately, most findings in this area are gathered after an illness, making preventive conclusions difficult;
- *Demographic variables such as age, sex, and social class:* The general influences of non illness risk factors also have bearing on adjustment, psychiatric, or behavioral problems. For example, "the risk of emotional problems in the general population increases with age, the emotional well-being of boys with a chronic physical illness is usually more affected than girls," but not always, and the risk is greater for those with a chronic illness as well as a disability;
- *External resources and support systems:* Adequate outside support can have a positive effect on the child and family's adjustment and is related to personal, financial and geographic factors. Social support typically includes available interpersonal networks and is seen as either protecting individuals from the detrimental affects of stressful life events or enhancing life regardless of life stress. There is also a dynamic interaction between the individual and the actual supports. However, the individual's perception or interpretation of the availability, size, and utility of these systems or individuals influences their effectiveness. An at-home single mother with more than one child may require and accept different kinds of help than a working couple with one child, newly relocated to another part of the country and feeling distant from family. Therefore providing support requires an understanding of an individual's preferred style, what is deemed supportive, and how it is most successfully accessed.

INCIDENCE AND CAUSE OF PSYCHOSOCIAL ADJUSTMENT PROBLEMS AND PSYCHIATRIC DISORDERS

The general consensus of the limited literature is that chronically ill children are at risk for psychological problems. There is, however, little agreement as to the incidence or cause. Estimates range from 9 to 37 percent, compared to 5 to 15 percent in the general population. Problems that do exist are most likely a normal response to illness-related issues and experiences rather than an indication of serious disturbance. This is not to say their significance should be ignored, only that they should be put in the correct context.

Definitive epidemiological statistics and results of intervention programs are difficult to report due to: existing resistance or denial of the problem from medical staff, the small numbers of children available with any one illness, the flaws inherent in collecting data from children with different illnesses, the lack of adequate comparative control groups, and the problem in accurately defining appropriate adjustment for these children. Because chronic illness itself is not likely to cause serious psychiatric disturbance, distinguishing between symptoms characteristic of a more systemic problem, such as depression or anxiety, and those resulting from the illness and situation, such as the stress of hospitalization or separation from parents, is of key importance. It is not unusual for children hospitalized for long periods of time to develop sleep, eating, or behavior problems due to constant waking by staff, physical restriction from intravenous lines, unappealing food, and to experience feelings of frustration and lack of control. A 5-year-old girl with leukemia may throw tantrum due to anxiety about being separated from her parents while receiving radiation treatments. These situations are instances of reactions precipitated by particular illness-related events. On the other hand, a preadolescent with hemophilia may be noncompliant with medical appointments and guidelines for curtailed physical activity as a result of conduct or learning problems unrelated to, but interfering with, the illness.

The most common psychological problems and areas of concern for mental health professionals are:

- *Internalizing problems:* anxiety, depression, fear, hopelessness, helplessness, loss of control, frustration
 - *Externalizing problems:* aggression, noncompliance, withdrawal
 - *Somatic complaints:* pain and impaired functioning
 - *Self-concept issues:* poor self-image, low self-esteem, changed or negative identity
 - *Social and educational difficulties:* academic and learning problems, decreased or deficient social competence
- particular problems that vary by illness are associated across different illnesses but for different reasons. For example, cognitive deficits are a possible complication

for children with leukemia who have had cranial radiation and for children with sickle cell disease if they have had strokes. As medicine and mental health services help more children, more are physically and emotionally healthier. A review of 60 studies of children ages 4 to 18 who had various chronic medical problems concluded that children with cancer were no more depressed than other children.⁴ Thus outcome research may show even smaller differences and more accurately delineate etiology and identify successful treatment. In fact most recently, cancer patient survivors were found to be functioning as well as, if not better than, their healthy counterparts on measures of aggression, antisocial behavior, and substance abuse.

MODELS FOR UNDERSTANDING THE INTERACTION OF ILLNESS AND ADJUSTMENT

Various models have been proposed for explaining and directing research on psychosocial adjustment, but most are generally constructed around concepts of stress and coping. Different theoretical frameworks describe the source of stress as:

- Emanating from the illness itself, as when a child with asthma has a flair up of breathing problems or must be hospitalized for a procedure; or from life stress and the environment, such as when a child changes schools or has parents who are divorcing;
- Derived from the interaction between specific illness risk factors (e.g. functional handicap and existing mental health problems) and protective or resistance factors (e.g. parental adjustment and problem solving ability).

One way to understand adjustment is by looking at the relationship between the source of the stress or threat and an individual's personal appraisal of stress. The basic stress and coping model posits that stress can be objective (e.g. shots hurt) or subjective (e.g. being afraid of shots). Successful coping strategies can be either problem-focused, addressing the objective source, or emotion-focused, directed at the subjective affective response.⁵ Active problem-focused coping efforts on the part of the child have proven to be more effective than avoidant coping or self-blame for concrete illness related medical needs. Research has yet to tailor treatment protocols due to an incomplete understanding of variables that influence treatment outcome. Age, gender, cognitive ability, and personality style are some factors that have been shown to independently or interdependently act on illness to impact outcome. For example, one study showed that girls with migraine headaches "profited more from (behavioral-psychophysiologic treatment) than boys, and those with a shorter history of migraine evidenced greater headache reduction as a result of treatment".⁶

Also unclear are the processes responsible for change. For example, a family-based intervention has been shown

to improve metabolic control of adolescents with diabetes but not family functioning, so the family-specific mechanism responsible for the change is not apparent. Thus successful functioning is dependent on isolating salient variables which affect treatment outcomes and refining interventions.

MANAGEMENT OF ILLNESS RELATED ISSUES: PREVENTION AND INTERVENTION

Due to the variability in illness type, degree of physical impairment, and the individual characteristics of the child's situation, identifying interventions requires careful assessment. Ideally, even though an understanding of the psychological issues is reached according to their medical origin, particular consideration should also be given to the individual and family variables that will influence intervention outcome.

The medical model for understanding illness prevails when a child's problems originate from a medical illness and the case is identified via the medical system. Prescribing an intervention can best be done by understanding the concrete medical/illness basis for the problem and its consequent psychological problem. For example, a child on chemotherapy with periodic low white blood cell counts may have restricted social activities. Psychologically, the child can feel he has no control over his body or illness, feel isolated, and therefore be angry and withdrawn. Intervention must target the source of the problem (perhaps with education or instruction on infection precautions) in addition to the resulting feelings and behaviors (perhaps by encouraging viable options for maintaining contact with classmates).

When, Why, and How to Intervene?

Planning an intervention is a complex process. The first step is to decide on a target problem and which aspect of the problem to attack. At first glance, a problem may seem straightforward, yet closer inspection usually reveals the interconnected, multidetermined nature of medically related psychosocial problems. For example, fluctuating insulin levels in a child with IDDM are most obviously related to inadequate insulin management. The cause of the poor management, however, is less obvious. Possible explanations include: improper technique, poor understanding of the disease, lack of parental supervision of a child who is self-administering insulin, and a child or parent's anger or denial.

The goals of preventive and targeted intervention include:

- "Mastery of anxiety and fears related to the illness and its management;
- A developmentally appropriate understanding of the illness;
- Compliance with treatment regimens;

- Integration of the illness into family life, including a balance between the needs of other family members;
- Successful adaptation to the important systems, such as the hospital, school and peers.⁷

Types of Interventions

Various interventions have been used with the child and/or those individuals in the home or school environments to meet the psychological demands imposed by the illness. Listed below are some of the most prevalent interventions.

Education: The importance of education about a disease – its cause, course, treatment, and long term effects – is often overlooked. But understanding of this information is influenced by the patient's age, cognitive ability, and psychological style. Children, like adults, vary as to the amount and type of information that is useful. Educating a child and family is not an all-or-nothing, single event. Accurate, honest information is the standard, but it must be transmitted in language appropriate to a child's age, when he/she is ready, and perhaps repeated at different times and in different formats. This also means refraining from making unrealistic promises such as "this won't hurt." A long-term view of education is also important. It is incorrect to assume that a child diagnosed with leukemia at 3 years of age, treated until age 6, who has relapsed at age 8 will know all there is to know based on experience alone. Misconceptions and inadequate and inaccurate information likely coexist and are confused with a more mature conceptualization. As children age, new issues become relevant. Genetic concerns with respect to marriage and pregnancy, for example, may emerge for the young adult with cystic fibrosis who is exploring intimate relationships. Education about appropriate parent-child interactions can decrease parents' overprotective tendencies and the child's adoption of the "sick" role. Illness information and guidance about interacting with the health care system and staff also can empower children and parents to be useful advocates and care partners.

Cognitive-behavioral strategies: Cognitive and behavioral techniques can help a child or teen identify the source of stress, change how it is perceived, and/or teach new behaviors. The goal of this approach is to reduce the impact of the stress, and to change feelings and consequent experiences. Cognitive components can include exploration of the link between thoughts and actions and training in more helpful ways of thinking about problems or symptoms. Behavioral components can include: breathing exercises, filmed modeling, systematic desensitization, behavioral rehearsal, positive reinforcement, distraction, and hypnosis-related techniques such as progressive muscle relaxation, focused attention and guided imagery. Play and art can also be utilized to improve mastery of medically-related behaviors or in conjunction with role play, imagery and relaxation strategies. Rehearsing bone

marrow aspirations or teaching self injection for IDDM via realistic dolls can gradually improve technique, shape compliance, and decrease fear.

Social skills training: Given that problematic peer relations can impact later psychosocial development, improving social functioning can have a protective effect. Interpersonal skill deficits can result from

- Lack of specific abilities
- Lack of opportunity
- Emotional or cognitive factors that interfere with performance. Effective training can result in improved self-esteem, confidence, and social competence. The components of social skills training programs vary, but typically should involve:
 - *Behavioral training:* this can include modeling, rehearsal, corrective feedback, and reinforcement
 - *Skill instruction:* direction and teaching for specific skills such as starting conversations, joining games, increasing peer acceptance
 - *Problem-solving:* skill training has been shown to be enhanced by training the cognitive processes needed for implementing learned skills. Teaching a child to learn to assess, negotiate, and plan action in social situations improves implementation and generalization of skills.

Remediation and Rehabilitation

Physical and academic remediation and rehabilitation for functional deficits can have a tremendous impact on psychological functioning. Early intervention in these areas allows children to be active, rather than passive participants in their illness management, and provides concrete, sequential feedback of improvement. Both the concrete progress and inherent message communicated by remediation and rehabilitation can counterbalance feelings of helplessness and hopelessness that often result from the vague, slow, long-term, sometimes static trajectory of medical improvement.

Family Therapy and Group Work

Given the interactive relationship between the child's illness and family and friends, working within a larger context can be helpful. Family work is often included in the management of the chronic illness with life-long duration, such as asthma and diabetes, where the family members can exert a positive effect on illness management. It can also be helpful for ventilation of feelings and clarification of misinformation by children and their siblings. Illness-related groups for children and adolescents with either similar or mixed illnesses can offer support through reality testing and shared problem solving. Going one step further, interventions done in school with respect to school re-entry or socialization can be considered as group work.

A child's social skills can be enhanced when work done individually is augmented with work done in the actual setting with peers. Providing guidance for handling school absence, physical difference, or answering questions can ease or eliminate teasing or isolation and improve peer relations.⁷

Examples of Implementation

The following two areas of concern typify issues that present to mental health professionals. The issue of school re-entry illustrates the use of intervention to minimize the immediate school-related problems secondary to a chronic illness and the prevention of later social and academic problems. Pain management represents a common acute problem, which if inadequately treated, can complicate medical treatment and lead to future adjustment and psychological difficulties.

School Integration or Re-entry

In easing the integration or return to school for the chronically ill child most efforts focus on all fronts: assisting the staff, classmates, and the child. The staff is helped by being educated about the illness and any necessary modifications that need to be made, such as a shortened day, restriction of foods or activities, and possible academic difficulties. The staff should also be guided as to how to explain the child's illness to the class. Consideration should be given to what the child and family want shared, what vocabulary to use, and if and how the child wants to participate in any teaching or transmitting of information. School staff should also be alerted to possible problem areas, such as upcoming treatments that could interfere with a standardized testing timetable, or a hospital admission that will prevent attendance at an important school dance. Academic concerns should be identified; either those that predate the illness or are newly caused by the illness. The child herself can be helped before returning to school by learning and practicing strategies to help her deal with potentially awkward peer interactions. Problem solving, role playing (perhaps related to explanations about the illness), and assertiveness training for possible teasing can be helpful. Having staff and/or the child talk directly to peers and having a child present a healthy and positive attitude can demystify misconceptions and increase acceptance.

Pain Management

Given that pain is multidetermined, resulting from the interaction of physical and psychological components, interventions focus on two areas. Pain perception is addressed by teaching the child, 1) "to regulate or modify his or her perception of pain through self-regulatory methods such as hypnosis, guided imagery, relaxation, and bio-feedback," and, 2) improving pain behavior through "the

manipulation and modification of environmental events that maintain pain behaviors.”

Assessment of a child who is referred for pain management entails gathering information from observers – parents, medical staff – as well as from the child. The child might be asked to describe the pain and to rate it by means of an objective scale. Unrealistic information and fears might need to be addressed and corrected through education. Other helpful strategies to develop a revised stress and coping cycle might include: relaxation techniques to train a new response when pain starts; doll play to help the child localize the pain, externalize feelings, and practice positive coping strategies; and self-hypnosis using patient-generated guided imagery. The parents can be educated about expected levels of pain to prevent them from overreacting to their child’s pain and they may be enlisted as coaches to assist the child in following through with a particular regimen of pain control. Decreased pain and anticipatory anxiety, increased sense of control and mastery, and enhanced ability to engage in normal activities resulting in prevention of later social sequel would indicate success.

OUTLOOK FOR THE FUTURE

Understanding how families change and develop has lagged far behind individual development. Families change over time although most family research has looked at them at only one point. Consistent with the notion that individuals, families, health care systems, and diseases interact over time, the need for prospective investigation of all these variables is crucial. Although the entire system is the overarching interest, understanding individuals, dyads, and triads within families is also important. Research at a family level of analysis can focus on either the entire family system or on individuals and subsystems conceptualized within a systems framework. That is, an individual’s responses, or sibling relationships can be seen as part of the larger system, which is consistent with family research. At times, incorporation of well-validated, accepted measures of individuals and couples may be preferable to less well-articulated and developed “family” measures. Studying one subsystem of the family is legitimate, so long as one specifies why the question fits with the larger understanding of the family.

There is an urgent need for consideration of developmental (children, parents, family) variables. Children of all ages have chronic diseases and the experience may be expected to vary by developmental stage. There are also

issues that are specific to children and childhood illness that have not been addressed in empirical studies. These include

- the locus of responsibility for medical compliance (parent vs patient),
- developmental ability to comprehend the illness and intricacies of treatment,
- school issues,
- relatively rapid developmental changes, and
- the impact of developmental stage on siblings.

Just as families change over time and evolve, so too do the course of our knowledge and the treatment of diseases. Advances in medical technology and changes in treatment regimens can change the impact of a disease dramatically. These changes demand current research that looks at the nature of the illness at present and makes many older studies obsolete.

The physical and psychological future for children and teens with chronic illness appears brighter than ever. With attention to their emotional needs, targeted interventions with a mental health professional, and guidance to parents, children’s adjustment and quality of life can be maximized. While awaiting medical cures or undergoing existing treatments, mental health care can help children and teens feel confident, effectively manage stress, adapt to their particular illness and grow to be independent, socially competent adults.

CHAPTER 201

Drugs in Psychiatric Disorders

Deepak Gupta, Ridhima Grover, Sameer Guliani

Child psychiatry is one of the upcoming and emerging superspecialties in the field of pediatric care in India. With the increase in awareness and early recognition of emotional and behavioral problems in children, the use of psychotropic drugs (those prescribed specifically to alter the behavioral or emotional state) in children has been on the rise across the world. The expansion of pharmacotherapy has been prompted, in part, by introduction of safer medications with better risk benefit ratio. Drug treatment represents a powerful way of altering the behavioral and mental states of children.

Approximately 7–15 percent of children and adolescents meet criteria for clinical psychiatric disorders.^{1,2} Problems of mental health and behavior in children are a multi-disciplinary problem and optimal approach is multi-modal treatment approach. The treatment should stress multi-modal intervention of which pharmacotherapy is only one part of the treatment, and should also address co-morbid psychiatric disorders.^{3,4} Medication has an important place in child psychiatric treatment, and expertise in the theoretical and practical aspects of drug use should be available in all child and adolescent mental health services (CAMHS). This chapter focuses on the pharmacological basis and use of psychotropic drugs in the management of various psychiatric disorders in children.

ASSESSMENT AND EVALUATION

A detailed multidisciplinary assessment is the stepping stone of any intervention. An ideal assessment of children should consider the total bio-psychosocial perspective and include a detailed neuro developmental history (Table 1). A thorough physical evaluation of the child is necessary to rule out organic (medical and neurological) conditions. Once the diagnosis has been established it should be re-assessed longitudinally to ensure accuracy, and for the development of any co-morbid conditions over time.

Table 1: Assessment and evaluation

Goals

- To determine a psychiatric diagnosis or target symptoms for which drug treatment might be indicated
- To identify and establish baseline measures for therapeutic targets
- To establish therapeutic contact and rapport with the child and the family

History

- Reasons for child's referral and current difficulties
- Target symptoms – frequency, duration, severity, precipitating, predisposing and maintaining factors
- H/o problems during antenatal, postnatal period, infancy and early childhood
- Language, social, cognitive, sensory, motor, physical and emotional development
- Temperament
- Sexual development and behavior
- Peer, siblings and family relationships
- Family and community background
- Strengths, abilities and areas of weakness
- Interests, hobbies, talents and vocations
- Exposure to traumatic or unusual circumstances
- Educational and vocational potential
- Present and past use of psychotropic and non-psychotropic medications, response to treatment and family's attitude towards intervention
- H/o substance abuse by the patient as certain medication can have a devastating interaction with illicit drugs
- Family h/o mental illness, suicide, substance use, neurological illness and specifically their response to psychotropic medication

APPROACH TO DRUG TREATMENT OF PSYCHIATRIC DISORDERS

One method to conceptualize treatment is to consider pharmacotherapy for core symptoms such as hyperactivity, inattention, self-injurious behavior, aggressive behavior,

sleep problems or the other approach is to consider it as a disorder as a whole such as depression, obsessive compulsive disorder, psychosis, etc. Periodic assessment and reevaluation is required to make a decision to go either for the symptom based approach or for the disorder based approach.

FACTORS ASSOCIATED WITH DRUG THERAPY AND RESPONSE IN CHILDREN

Neurodevelopmental factors: Various neurodevelopment factors may alter the response of children to drugs that have proven efficacy in adulthood.⁴ Parasympathetic and sympathetic modulation, varying hepatic metabolism, increase ketosteroid levels, different hormonal milieu and incomplete maturation of the neurotransmitter system may affect the drug response as the child grows. Therefore as child matures, treatment plans need to be revisited and adapted to changing individual.

Pharmacokinetic and pharmacodynamic factors: Very less is known about pharmacokinetics and pharmacodynamics of psychotropic drugs in children, than in adults. Age, sex, weight, disease state, absorption, distribution, metabolism and excretion may all alter the drug response in children. As mentioned above, neurodevelopmental factors are important to be considered.

Drug interactions: Simultaneous administration of psychiatric drugs and other drugs for physical ailments can have serious adverse reactions if ignored. Knowledge of these interactions of psychotropic drugs with drugs such as antibiotics, antihistaminics and anticonvulsants are important in children. Polypharmacy is to be avoided unless it is absolutely necessary with close monitoring and revisiting at regular intervals.

Lack of research in children: Very few psychotropic drugs are exclusively used for specific conditions in children such as atomoxetine and stimulants for attention deficit hyperactivity disorder (ADHD), as most of the psychotropic drugs are developed and researched in adults. This may be due to various ethical and consent issues, which has deprived children with psychiatric disorders with many drug options. Simultaneously, short and long-term side effects including developmental impact are not known in children for most of the psychotropic medicines. Also except for few psychotropic drugs, most are not available as child friendly preparation, which interferes with the compliance in children.

Other factors: Inadequate assessment with rapid jump to drug treatment, presence of co-morbidity (presence of more than one disorder simultaneously), drug treatment as the only treatment, inadequate understanding of psychosocial factors, and lack of trained child mental health professionals are the other factors which contribute to drug therapy and response in children on a longer term.

ETHICAL ISSUES

The main purpose of professional ethics in relation to pediatric psychopharmacology is that children are treated upon in a safe, effective and fair manner so that they or the society are benefited from such treatment with no or minimal adverse effects on the children.^{5,6} Psychopharmacology with children and adolescents has to face an inherent paradox: on one hand, it is unethical to use treatment procedures without scientifically proved efficacy; and on the other hand, there are ethical problems to examine the efficacy of treatment methods scientifically. This contradiction has been called the “inherent paradox of clinical trials in psychiatry”.

Few issues, which should be considered while treating children with psychotropic drugs, are:

- Only children with impairing psychiatric symptoms or disorders should be treated with medication.
- Medication should be chosen in a manner that it affects the maximum possible target symptoms.
- Medication should be initiated at the lowest possible dose and dose titration should be gradual in general.
- Medication chosen should not improve one symptom and worsen others.
- The children should not suffer from undue side-effects of psychotropic drugs.
- Children should not be exposed to new unapproved medication unless justified, and with consent from parents.
- Any drug treatment for psychiatric disorders should not be thought of as indefinite. It must be determined, from time to time, whether it is necessary to continue medication.
- Adequate information about the need for medication, and for symptoms it is being prescribed, how it is to be administered and for how long, what improvement to expect, side effects, and other treatment options available, impact of treatment on child psychiatric disorder and his life should be discussed with parents.
- An attempt should be made to include children in the process of management and they should be told about their psychiatric problems and treatment and medication in an age appropriate manner. This will go a long way in increasing their willingness and compliance for treatment.

DRUG TREATMENT OF SPECIFIC DISORDERS

In recent years, the emphasis on evidence based practice has led to a more rational evaluation of the use of drugs in child psychiatry with more evidence existing for disorders such as attention deficit hyperactivity disorder (ADHD) and obsessive compulsive disorder (OCD). Table 2 illustrates the conditions where drug treatment plays a significant role along with the first line commonly prescribed

Table 2: Treatment of specific disorders where drugs play a significant role

<i>Disorder</i>	<i>Commonly used (First line)</i>	<i>Dosage</i>	<i>Alternative (Second line)</i>	<i>Others (Third line)</i>
ADHD	Stimulants Methylphenidate Dexmethylphenidate Lisdexamfetamine	0.5–1.5 mg/kg	Tricyclic antidepressants TCA's (imipramine) Alpha-agonists (clonidine, guanfacine)	Antipsychotics Selegiline Buspirone Venlafaxine Modafinil Bupropion
Tourette's syndrome	Atypical Antipsychotics Risperidone Clonidine	1.0–1.5 mg/kg 0.25–2 mg/day 50–300 mcg/day	Typical antipsychotics (haloperidol, pimozide) Selective Serotonin Reuptake Inhibitors (SSRIs) TCA's (imipramine)	Tetrabenazine Anticonvulsants Botulinum toxins Benzodiazepines
Obsessive compulsive disorder (OCD)	SSRI's* Fluoxetine Sertraline Paroxetine Fluvoxamine Citalopram Escitalopram	20–60 mg/day 50–200 mg/day 20–60 mg/day 50–200 mg/day 20–60 mg/day 5–20 mg/day	Clomipramine ²² (50–200 mg/day)	Benzodiazepines Buspirone Atypical Antipsychotics (risperidone)
Psychosis/schizophrenia	Atypical Antipsychotics Risperidone, Aripiprazole Olanzapine Quetiapine Paliperidone	1–6 mg/day 5–20 mg/day 5–20 mg/day 50–500 mg/day 3–12 mg/day	Typical antipsychotics (haloperidol)	Clozapine for treatment resistance ²¹
Depression	SSRIs* Fluoxetine Sertraline Paroxetine Citalopram Escitalopram	20–40 mg/day 100–200 mg/day 20–40 mg/day 20–40 mg/day 10–20 mg/day	Tricyclic antidepressants (imipramine) Atypical antidepressants (venlafaxine, mirtazapine, bupropion)	Mood stabilizers (lithium sodium valproate) Atypical antipsychotics (olanzapine)
Bipolar disorders	Mood stabilizers Lithium Sodium valproate Carbamazepine Oxcarbamazepine Atypical Antipsychotics Olanzapine Risperidone Quetiapine Aripiprazole	600–1200 mg/day (0.4–1.0 mEq/L)* 500–2000 mg/d (50–100 mg/L)* 300–1200 mg/d (5–10 mg/L)* 300–1200 mg/d 5–20 mg/day 1–6 mg/day 100–600 mg/day 5–20 mg/day	Benzodiazepines (lorazepam, clonazepam) Anticonvulsants (lamotrigine)	Other anticonvulsants (topiramate) SSRIs (if depression persists) * Blood levels

*Warning: All SSRI's except fluoxetine carry risk of increasing suicidal behavior and require frequent monitoring

drugs with their dosages.^{4,7-12} Beside first line drugs, there are second line and third line drugs (Table 2) which need to be prescribed when the first line drugs fail to give adequate response or need to be stopped due to undue side effects.

There are certain psychiatric disorders in children and adolescents^{4,7,9,10,13-18} where the medication may not play a significant role and where drugs are used to ameliorate certain specific target symptoms (Table 3).

Table 3: Treatment of specific disorders where drugs play a less significant role

<i>Disorder</i>	<i>Target symptoms</i>	<i>Drugs used commonly</i>	<i>Other drugs used</i>
Autistic spectrum disorder (ASD)	Aggression Hyperactivity Self-injurious behavior Stereotype behavior Social deficit	Atypical antipsychotics (risperidone, aripiprazole) SSRIs (fluoxetine) Clonidine	Buspirone Benzodiazepine Naltrexone Mood stabilizers Donepezil
Mental retardation (MR)	Behavioral problems Aggression Hyperactivity Emotional problems Depression Anxiety	Atypical antipsychotics Clonidine Stimulants SSRIs	Buspirone Benzodiazepine Mood stabilizers
Conduct disorders	Aggression	Atypical antipsychotics Mood stabilizers	Buspirone Benzodiazepine
Anxiety disorders	Separation anxiety Fear/phobias Social anxiety Selective mutism Generalized anxiety Panic attacks	SSRIs Fluoxetine Sertraline Paroxetine Fluvoxamine Citalopram	Buspirone Benzodiazepine Tricyclic antidepressants Atypical antidepressants
Enuresis	Bed wetting	Desmopressin	Imipramine Amitriptyline Carbamazepine
Sleep disorders	Insomnia Night terror Nightmare Night walking Hypersomnia	Benzodiazepine Melatonin Zolpidem Zalapelon Stimulants (methylphenidate) Modafinil	Tricyclic antidepressants Atypical antidepressants
Eating disorders	Binge eating	SSRIs	Topiramate

MAIN CLASSES OF DRUGS USED IN PSYCHIATRIC DISORDER

Stimulant drugs including methylphenidate (only one available in India), and dexamphetamine, are widely used world-wide and are effective in the treatment of attention deficit hyperactivity disorder (ADHD).

Despite the extensive clinical and pharmacological knowledge about stimulants, the basis for their efficacy in ADHD remains unclear. Stimulants act by releasing monoamines from nerve terminals in the brain. Noradrenaline and dopamine are the most important mediators but serotonin release also occurs. They increase intrasynaptic concentration of dopamine by blocking the dopamine transporter and by displacement of monoamines from synaptic vesicles. The core behavioral response in child with ADHD seems to be an improved ability to 'inhibit', and therefore enhance persistence in motor and cognitive functions.

The different stimulants have slightly different half-lives and this is important in clinical practice. Methylphenidate has the most rapid onset of action (1–3 hrs) and

shortest half-life (2–3 hrs) so that the clinical effect wears off after 4–6 hrs. Long-acting preparations (available in India now) are appealing for whom the standard formulations act briefly, those who experience severe rebound hyperactivity, or in whom frequent dosage is impractical.⁷ There is little evidence for the development of tolerance in children taking stimulants for treatment of ADHD.

Although the stimulants are safe, dose-dependent side effects may occur, and are similar for all stimulants. The most common are reduced appetite, stomach ache, headache, jitteriness, delayed sleep onset, increased blood pressure and pulse, and dysphoria which usually wear off or may be reduced by lowering the dose or switching to alternative drug. There is little evidence that stimulants produce a decrease in the seizure threshold or drug addiction results from the prescription of the stimulants for ADHD.⁴ Growth retardation resulting from long-term stimulant use is actually small and it can be minimized by using drug free periods if given for long-term. The results of the Multimodal Therapy of ADHD (MTA) study

revealed a more persistent effect of stimulants on decreasing growth velocity than have most previous studies, particularly when children were on higher and more consistently administered doses.²⁵ The effects diminished by the third year of treatment, but no compensatory rebound effects were found. However, diminished growth was in the range of 1 to 2 cm. An uncommon additional significant adverse effect of stimulants is the occurrence of hallucinations and other psychotic symptoms. Although concerns have been raised about the rare occurrence of sudden cardiac death among children using stimulant medications, sudden death in children on stimulant medication is extremely rare, and evidence is conflicting as to whether stimulant medications increase the risk of sudden death. It is important to expand the history to include specific cardiac symptoms, Wolf-Parkinson-White syndrome, sudden death in the family, hypertrophic cardiomyopathy, and long QT syndrome, and if present, baseline ECG should be done before starting stimulants.

There is abundant evidence for the short-term beneficial effects of stimulants for the treatment of ADHD. Stimulants not only improve the core symptoms but also have a wide variety of effects on academic, behavioral, social and cognitive domains. Greater hyperactivity, inattention, clumsiness and absence of emotional disorder predicts a greater response to methylphenidate.⁸ The MTA (multimodal treatment study of children with ADHD), New York-Montreal long-term ADHD treatment study and Preschool ADHD treatment study (PATS) provide strong support for the role of medication in treating children with ADHD across all age group.^{23,25} The findings from the MTA study suggested that more than 70 percent of children and youth with ADHD respond to one of the stimulant medications at an optimal dose when a systematic trial is used. Because stimulants might produce positive but suboptimal effects at a low dose in some children and youth, titration to maximum doses that control symptoms without adverse effects is recommended. Stimulants can be effectively titrated over a 3 to 7 days period. Although they are being used in preschool children but methylphenidate is not recommended to be used before the age of 6 years and only dexamphetamine has been recommended to be used before the age of 6 years.¹⁹ The presence of comorbid conditions such as anxiety disorders, tics and autism may alter the response to stimulant medication and requires cautious treatment. Evidence suggests that the rate of metabolizing stimulant medication is slower in children 4 to 5 years of age, so they should be given a lower dose to start, and the dose can be increased in smaller increments. Maximum doses have not been adequately studied.

Because norepinephrine-reuptake inhibitors and α 2-adrenergic agonists are newer, the evidence base that supports them—although adequate for FDA approval—is considerably smaller than that for stimulants. Only 2 medications have evidence to support their use as

adjunctive therapy with stimulant medications sufficient to achieve FDA approval: extended-release guanfacine and extended-release clonidine. Other medications have been used in combination off-label, but there is currently only anecdotal evidence for their safety or efficacy, so their use cannot be recommended at this time.²⁴

A few medications have shown benefit for challenging or repetitive behaviors, and the clearest evidence favors atypical antipsychotics risperidone and aripiprazole. Significant adverse-effect profiles, however, make it clear that although these drugs are efficacious, caution is warranted regarding their use in patients without severe impairments or risk of injury.

The recent Research Units on Pediatric Psychopharmacology (RUPP) study on the treatment of the behavioral problems of children with autism is the largest published study undertaken to try to identify pharmacotherapeutic agents that can be useful for these often severely disruptive children. The results showed a significant reduction in irritability score in children who were prescribed atypical antipsychotic risperidone as compared to placebo group.²⁶ Insufficient evidence is available to judge the potential benefit or adverse effects of all other medical interventions currently used to treat autism.²⁷

The selection of the specific SSRI in treating depression should be based on the optimum combination of safety and efficacy data. The patient and family should be informed about the possible adverse effects (clinicians may use a checklist) including possible switch to mania or the development of behavioral activation or suicidal behavior. Once the antidepressant is started, and if tolerated, the clinician should ensure an adequate trial up to the maximum dose and duration.²⁸

The Treatment for Adolescents with Depression Study (TADS) was a randomized controlled trial that evaluated the effectiveness of fluoxetine hydrochloride therapy, cognitive behavior therapy (CBT), and their combination in adolescents with major depressive disorder. The study concluded that in adolescents with moderate to severe depression, treatment with fluoxetine alone or in combination with CBT accelerates the response. Adding CBT to medication enhances the safety of medication. Taking benefits and harms into account, combined treatment appears superior to either monotherapy as a treatment for major depression in adolescents.²⁹

The Pediatric OCD Treatment (POTS) Study, a balanced, masked randomized controlled trial conducted in 3 academic centers in the United States randomly assigned participants to receive CBT (Cognitive behavior therapy) alone, sertraline alone, combined CBT and sertraline, or pill placebo for 12 weeks. The results showed better response with combined treatment with CBT along with pharmacotherapy. Hence, children and adolescents with OCD should begin treatment with the combination of CBT plus a selective serotonin reuptake inhibitor or CBT alone.³⁰

Table 4: Other classes of drugs to treat psychiatric disorders

Drug	Mechanism of action	Actions	Side effects	Pharmacokinetics	Primary indications	Possible indications
Benzodiazepines						
Lorazepam	Enhancement of inhibitory effect of GABA acting GABA-A receptors	Sedative Anxiolytic Anticonvulsant	Confusion Amnesia Tolerance Dependence Impaired coordination	Well-absorbed orally Inactivated by hepatic metabolism Half-lives varies	Sedation	Acute aggression Anxiety disorders
Antidepressants						
Tricyclic (Imipramine)	Norepinephrine, serotonin, dopamine reuptake inhibitors	Antidepressants Anxiolytic Sedative	Tricyclic-sedation, dry mouth, constipation, giddiness, cardiotoxicity	Well-absorbed orally Half-lives varies b/w drugs and individuals	Depression Obsessive-compulsive disorder (OCD)	Anxiety disorders ADHD Autistic spectrum disorder (ASD) Nocturnal enuresis
Atypical (Mirtazapine)	Monoamine receptors antagonists		SSRIs-nausea, agitation, insomnia, headache Atypical-varies	Give rise to long-lived active metabolites Clinical response 2-4 weeks		
Mood stabilizers						
Sodium valproate	Uncertain weak GABA-enhancing and Na-channel blocking action	Antiepileptic Antimanic Sedative	Nausea, somnolence Weight gain, hepatotoxicity	Well absorbed orally Half-life 12-15 hours		Aggression Kleine-Levin syndrome (KLS)
Carbamazepine	Na-channel blocking action	Antiepileptic Antimanic Sedative	Nausea, dizziness, tics Leukopenia and hepatotoxicity at high plasma levels	Well-absorbed orally Half-lives varies 12-60 hrs, tending to decrease because of induction of metabolizing enzymes	Mania Bipolar disorder	
Lithium	Uncertain second messenger systems	Antimanic	Nausea, tremor, polyuria, ataxia, confusion	Renal excretion Monitoring of plasma concentration		Autistic spectrum disorder (ASD) ADHD Aggression sadation
Antipsychotics						
Typical (Haloperidol)	Dopamine receptor antagonist	Sedation Antipsychotic	Extrapyramidal side effects Sedation, weight gain, Hyperprolactinemia	Well-absorbed orally Inactivated by hepatic metabolism Half-lives varies	Psychosis Tourette's/ Tic disorder	Autistic spectrum disorder (ASD)
Atypical (Risperidone)	Serotonin and glutamate receptors modulation		Metabolic side effects			
Clonidine	Partial agonist at alpha-2 adrenoceptor	Sedation ↓ sympathetic activity	Hypotension, sedation, dry mouth, bradycardia	Well-absorbed orally Plasma half-life 12 hours but pharmacological effect 2-4 hours	ADHD Tics/ Tourette's disorder	Nocturnal enuresis
Atomoxetine	Selective norepinephrine reuptake inhibitor	↑ concentration ↓ impulsivity	Somnolence, decrease appetite, fatigue, dry mouth	Well-absorbed orally Plasma half-life 5 hours	ADHD	

Beside stimulants, various other classes of drugs^{4,7,9-15,20,23} are used to treat psychiatric disorders in children and adolescents (Table 4).

CONCLUSION

Prescribing habits for treatment of psychiatric disorders in children and adolescents continue to be determined as much by dogma as by evidence. Treatment decisions can only be made on the basis of rigorous assessment and diagnostic evaluation. Routes into mental disorders can be developmental, genetic or environmental but etiology does not generally determine treatment in psychiatry. Clearly the final common pathway to behavioral, emotional or cognition dysfunction is through alteration in the brain function, and an effective part of treatment may be to use drugs which act on the brain. With better understanding of psychiatric disorders in children and adolescents, newer psychotropic drugs with better side-effect profile and higher degree of precision will be an asset to the clinician dealing with children and adolescents.

KEY POINTS

Drug therapy in children must take into account the child's environmental influences and should be part of an overall multimodal treatment plan that addresses the relevant individual, familial and cultural issues.

Drug therapy can be symptom based or disorder based but should be based on "Start Low, Go Slow".

Cautious, judicious drug therapy in children can make a difference to their suffering and assist them in the maintenance of their expected developmental trajectory.

Child Abuse: An Unrecognized Problem

Rajesh Sagar, Raman Garg, Manju Mehta

CONCEPTS AND DEFINITIONS

Child abuse is one of the major problems affecting children today. Child abuse causes more physical and psychological morbidity than does most pediatric illnesses. It is not a new phenomenon. Lynch (1885) points out that the incidents of child abuse are referred to in literature dating back to the second century AD but still no exact statistics are available. Kempe and colleagues (1962) coined the term battered child syndrome. It led to increased interest in, and recognition of, what come to be known as non-accidental injury. Nowadays, the simple term child abuse is generally preferred. This covers not only physical abuse but also sexual, emotional abuse and neglect. Child abuse affects children of all ages.

Though this problem of child abuse of children in India is increasing, it has failed to draw the attention of pediatricians, psychiatrists and sociologists in our country. The public and government also have not yet recognized it as a serious problem.

The study of child abuse and neglect has been hindered by the failure to establish a consensus regarding an objective operational definition of what constitutes abuse. Starr (1988) stated that there are four elements involved in defining child abuse:

- The intentionality of the act
- The impact of the act on the child
- Value judgments about the fact
- The cultural and societal standards upon which the act is evaluated.

At present, there is no single, specific definition on child abuse in India. The definition of child abuse can be gathered from a number of articles in the Constitutions of various countries.

But still child abuse has been defined medically as any interaction or lack of interaction between a child and his/

her caregiver which results in nonaccidental harm to the child's physical or developmental state. "Neglect" refers to denial of health or other basic needs, emotional deprivation or mistreatment or failure to provide proper parenting. It is now a broader concept applied to acts of omission and commission by parents and caretakers that harm or potentially harm children.

Incidence

There are wide variations in the reported incidence of child abuse and neglect. This is no doubt due in part to real difference in the incidence in different populations, but the variations are also due to definitions of what constitutes abuse and to the use of different methods of ascertainment. In the absence of public and government interest in the problem of child abuse no statistics have been compiled in India to indicate the incidence of abuse. Considering the poverty, illiteracy, and large size of families in India, it could be said that 5 to 15 per 1,000 children are abused by parents and employers in our country. In India, the 1991 census put the figure of child abuse at 16.5 million, i.e. 5.5 percent of the total child population. A study by Kewalramani (1990) in Rajasthan was focused on 167 children in the age range of 10 to 16 years. Of the 167 case studies, 124 were cases of physical abuse, 23 of sexual abuse and 103 of emotional abuse (the total is more than the case studies because many children were victims of multiple abuses). Further, of total cases studied, 61.7 percent were boys and 38.3 percent were girls. Incidents of physical and emotional abuses were more common among boys and sexual abuse among girls. In a 1999 report by the Tata Institute of Social Sciences, a study done in 1994 and 1995 with 150 minor-age girls in Mumbai, India showed that 58 of the girls surveyed had been sexually abused before age 10. Of this number, 50 had been abused by a family member or friend of the family.

Etiology

The etiological factors of child abuse and neglect are complex. Most experts believe that child abuse occurs as a result of the combined outcome of various factors that may occur both in the patients and in the child in conjunction with the environment.

Mac Millan (2000) summarizes the “risk indicators” that have been found to be associated with abuse. For physical abuse there are:

- Child factor
 - Male sex
- Parental factors
 - Young maternal age
 - Single-parent status
 - History of childhood experience of physical abuse
 - Spousal violence
 - Unplanned pregnancy or negative attitude toward pregnancy
 - History of substance abuse
 - Social isolation or lack of social support
- Social factors
 - Low socioeconomic status
 - Large family size

For sexual abuse known ‘risk indicators’ are:

- Child factor
 - Female sex
- Parental factors
 - Living in a family without a natural parent
 - Poor relationship between parents
 - Presence of a stepfather
 - Poor child-parent relations.

The above factors are just correlates of abuse, not necessarily causes. As their presence should alert us to the possibility of abuse and if several of them are present, to the probability of it (Flow chart 1).

Types of Child Abuse

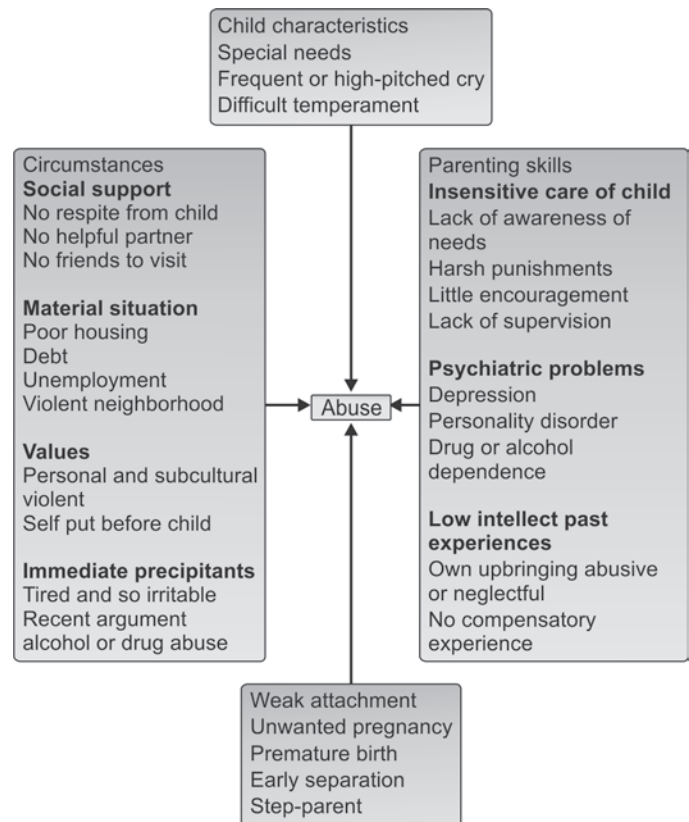

Four main types of child abuse occur—physical abuse, neglect, emotional abuse, and sexual abuse. More than one type of abuse may occur at any one time, and a child who has been subject to one form of abuse is more likely to suffer another in the future.

Physical Abuse

Physical abuse is still the prototype when we discuss about child abuse. Physical abuse occurs when an adult inflicts a physical injury on a child more severe than is culturally acceptable. It is sometimes more difficult than one might think to draw the line between acceptable and nonacceptable violence.

The cardinal feature of the clinical presentation of physical abuse is a physical injury for which the explanation provided is unsatisfactory. The common forms of nonaccidental injury result in multiple bruising, burns, abrasions,

Flow chart 1: Factors predisposing to abuse

bites, torn upper lip, bone fractures, subdural hematoma, and retinal hemorrhage, etc. Other forms of physical abuse include deliberate suffocation and poisoning.

Variants of Physical Abuse

Munchausen syndrome by proxy, also known as factitious illness by proxy, refers to a child being presented to doctors by a parent (almost always the mother) who has induced the illness. The mother brings the child to the hospital repeatedly for investigations. Forms of fabricated illness include respiratory arrests, apparent bleeding from a variety of orifices, poisoning, seizures, skin rashes, and fever, etc.

Shaken baby syndrome consists of intracranial damage (hemorrhage, shear) injuries created by violently shaking a child. Most victims are under 2 years of age. About 15 to 25 percent of identified victims die and most of the rest have neuromotor, visual and cognitive impairment.

Failure to thrive simply refers to less than expected weight gain. Until the later half of 20th century it was presumed that failure to thrive was always the result of an organic disorder. Only recently, we have come to know that a child's environment may be the cause of growth failure. This group comprises nonorganic failure to thrive. There is usually a background of prolonged neglect or physical abuse in these children.

Sexual Abuse

Sexual abuse may occur in the absence of other forms of abuse or neglect, and it may continue for long periods undetected. Girls are abused more often than boys. The abuse may consist of anything from fondling of the child's breasts or genitals to vaginal or anal intercourse. Another form of sexual abuse is the sexual exploitation of children in pornographic movies, videotapes and photographs. Approximately 85 percent of sexual abuse is committed by someone known to the child. The abuser may be parents, step-parents, other relatives and foster parents. Sexual abuse is equally prevalent in all socioeconomic classes whereas physical abuse and neglect may be more common in low socioeconomic classes. Incest is believed to be the most frequent child sexual abuse in India. Given the Indian attitude toward family loyalty, it is most difficult to prosecute.

Emotional or Psychological Abuse

The emotional and other psychological needs of many children are not adequately met in the families. Sometimes, it is very difficult to assess the severity of family failure to meet its children's needs so as to justify the use of the term emotional abuse, although extreme cases are easily identified. Elements include:

- Extreme hostility and criticism.
- Deprivation of attention.
- Rejection and withdrawal of affection.
- Threats of abandonment.
- Inappropriate stresses and demands.

Neglect

In contrast to persons who commit physical and sexual abuse, the perpetrators of neglect almost always are unaware that they mistreat their children. Neglect refers to an absence of appropriate care rather than positively inappropriate acts. Most areas of care may be involved:

- *Lack of physical care*—includes undernutrition, recurrent infection, unkempt dirty appearance, etc.
- *Lack of medical care*, with failure to bring the child for immunizations, failure to seek appropriate medical help for illnesses and accident.
- *Lack of enforced house routines*, rules and supervision, leads to an increased rate of accidents at all ages, including domestic and road traffic.
- *Lack of emotional warmth and availability*.
- *Lack of cognitive stimulation and encouragement in constructive pastimes*.

OUTCOME FOLLOWING CHILD ABUSE

It has been noted that less attention has been given to the consequences of child abuse. General statements cannot

be made about the outcome of child abuse. Many factors affect this, including the nature, severity, and duration of the abuse; the personality strengths and previous adjustment of the abused individual; the stability of the abused child's family and its ability to provide needed support to the child; and the treatment subsequently provided to the abused individual. What is known, however, suggests that there is no single pattern of emotional or behavioral difficulties that characterizes all abused children. To date only a few specific outcomes have been linked with specific patterns of abuse. This is partly due to wide overlap of types of abuse, so it is hard to study pure abuse of one type.

Consequences of Physical Abuse

Emotional Regulations

Four general patterns may be seen:

- Emotional blunting and lack of social responsiveness.
- Depressed affect with sad facial expressions, withdrawal and aimless play.
- Emotional lability, with sudden shifts from engagement and pleasure to withdrawal and anger.
- An angry emotional state with disorganized play and frequent outbursts in response to slight frustrations.

Formation of Attachments

Abusive parenting is associated with insecure attachments, which in turn often lead to later psychopathology in infant. Particularly common are the disorganized response, characterized by fear, disorientation, odd expression and freezing, etc.

Development of Self-concept

Abused children find it difficult to talk about themselves, and especially about their negative feelings. Measures show low self-worth and low self-competency ratings.

Physical Effects

A variety of physical consequences may result from child abuse. These include psychological short stature, non-organic failure to thrive, blindness, permanent mental retardation, cerebral palsy, physical injuries and death.

Symbolic and Social Development

Play is reduced in quantity, and its quality is impoverished, with an increase in routine, stereotyped activity. Abused children show less sensitivity to the emotions of others, more negative expectation of people and less trust in them.

Cognitive Development

Both language and nonverbal abilities are less well-developed than in nonabused controls.

Emotional and Behavioral Disorders

Acute psychiatric manifestations of child abuse have been shown in the Table 1. Increased incidence of various disorders like ADHD, aggression, PTSD, anxiety disorders, dissociative disorder, depression, substance abuse and suicide have been found in various studies.

CONSEQUENCES OF SEXUAL ABUSE

Negative effects to physical health specific to childhood sexual abuse include urinary tract problems, gynecological problems, elevated risk for sexually transmitted diseases (including AIDS), and elevated risk for pregnancy.

The medium and long-term psychiatric outcome for children who have been sexually abused frequently involves persisting dysfunction. These have been shown in Table 2.

The consequences of neglect and emotional abuse have been less well-studied, possibly because these forms of abuse often overlap with other types. However, it seems likely that these children will often fail to achieve their full potential for growth, and that they will show mild-to-moderate learning disabilities.

There are some factors, which may predict the outcome of child abuse to some extent but no conclusive studies are available regarding these factors (Table 4).

Diagnosis and Management

Divergences between the observed injury or condition and the history usually give a clue for determining whether abuse may have occurred. Without observable injuries or condition, history is the key component of diagnosis. A good evaluation starts with obtaining a thorough history

and completing a comprehensive physical examination of the child. Documentation of all injuries is crucial. Behavioral symptoms are generally nonspecific, consisting of indicators of stress (e.g. secondary enuresis, depression, aggression, deteriorating school performance). The management of children suffering from different types of abuses almost follows similar lines, except some investigation part (Table 3).

Table 2: Long-term manifestations of sexual abuse

Emotional

- Depression
- Panic disorders
- Phobias
- Somatization
- Hysteria

Interpersonal

- Pseudomaturity/regressive immaturity
- Overcompliance/aggressiveness
- Poor peer relations

Cognitive/perceptual

- Hallucinations
- Detailed knowledge about sex
- Inability to concentrate at school
- Learning disabilities
- Languages disabilities

Table 1: Acute psychiatric manifestations of child abuse

- Behavioral
 - Acting out
 - Aggressive
 - Delinquent
 - Hypersexual
 - Self-defeating
 - Acting in
 - Avoidant
 - Psychosomatic
- Emotional
 - Depressive
 - Anxious
 - Self-deprecating
 - Hypomanic
- Cognitive
 - Inattention
 - Memory dysfunction
 - Academic difficulties
- Interpersonal
 - Family dysfunction
 - Peer conflicts

Table 3: Signs and symptoms that arouse concern about physical abuse or neglect

Subnormal growth

- Weight, height, or both less than the 5th percentile for age
- Decreased velocity of growth

Head injuries

- Torn frenulum of upper or lower lip
- Bilateral black eyes with history of single blow or fall
- Retinal hemorrhage
- Intracranial trauma

Skin injuries

- Bruise or burn in shape of an object
- Bite marks, pinch marks, slap marks
- Bruises of various colors (cheek, buttocks, etc.)

Injuries of the gastrointestinal or genitourinary tract

- Recurrent vomiting or diarrhea witnessed only by parent
- Chronic abdominal or perineal pain with no identifiable cause

Bone injuries

- Rib fracture in the absence of major trauma such as a motor vehicle accident
- Multiple fractures in various stages of healing
- Complex skull fracture
- Metaphyseal long-bone fracture in an infant

Laboratory studies

- Impulsive or physiological inconsistent laboratory results
- Positive toxicologic tests in the absence of a known ingestion or medication

Table 4: Prediction of intervention success

<i>Factor</i>	<i>Better outcome</i>	<i>Worse outcome</i>
Parental	Acceptance of problems Compliance with treatment Normal personality Supportive partner No psychiatric disorder	Denial of problems Refusal to cooperate Personality problems Abusive partner Substance abuse Psychosis
Characteristics of abuse	Less severe injuries	Severe injuries
Interaction with child	Normal attachment Responsive care-giving	Disordered attachment Insensitive care-giving
Child	Healthy child	Special needs—physical or learning problems
	Resilient response to abuse	Extensive psychopathology
Circumstances	Good local childcare Informal networks	No facilities Social isolation
Professional intervention	Well-trained and resourced Therapeutic relationship	Few resources or skills Lack of engagement

Physician's Basic Responsibilities

The first step of involvement in suspected child abuse cases is to acknowledge that the problem exists. Some physicians refuse to believe that parents have injured their own children. Once the physician acknowledges that the abuse and neglect occur; he must maintain a high index of suspicion for cases of abuse and neglect. Usually parents themselves do not suggest abuse as a possible cause of their child's condition; therefore, the physician must constantly consider the diagnosis. However, many times the physical evidence is not conspicuous and a careful interview with the child and his parents will point out discrepancies between the history and observed condition. The physician then must make a medical judgment as to whether the physical signs and symptoms are plausibly explained by the history offered. The physician's consideration of abuse or neglect should not be biased by the socioeconomic, occupational or educational level of the parents.

The next step, probably one of the most difficult duties that the physician must take is to discuss with the parents that child abuse is in differential diagnosis of their child's problem. He must maintain his objectivity, control his hostility and be honest with the parents. It is when the physician confronts the parents with possible diagnosis that many parents are alienated from that physician. If handled properly the parents can be informed of the suspected diagnosis, will cooperate with the recommendations of the physician.

The physician's next responsibility is to protect the child. This may be done initially by admitting him in a hospital and contacting an agency that handles child protection matters in his community. Once the child is in hospital and is at least temporary protected from his

parents, an appropriate evaluation of the child's physical and development problem is necessary. Consultations from surgeons, ophthalmologists, orthopedists, psychiatrists, psychologists, and radiologists may be necessary as indicated to evaluate and document individual physical and psychological manifestations of the abuse. During this evaluation procedure everything should be documented in the medical chart.

The physician must be aware that his inputs into a case of suspected child maltreatment should be limited to that of a physician. Judges, social workers, NGOs involved in child protection issues all have their roles to play; the physician should not think that he can perform all the necessary functions because child abuse is a multidisciplinary approach. The physician may get caught up in the non-medical aspects of the case, forgetting the child's physical and psychological problems.

Physical Abuse

A physically abused child may be brought to medical attention when the injury persists or worsens. To diagnose physical abuse one requires having an understanding of child development and the biomechanics of injuries, and skills in eliciting an appropriate history. There are certain indicators that may increase the suspicion for physical abuse (Table 3).

Sexual Abuse

The diagnosis of sexual abuse is made most often by history. A high index of suspicion should be maintained. It is probably unusual for children to lie or fantasize about being sexually abused. All family doctors, pediatricians, and child psychologists should feel competent to make

general enquiries concerning the possibility of child sexual abuse by encouraging the child to talk about events that worry them and suggesting there might be problems the child may find it difficult to discuss. Anatomical dolls and drawings by the child are useful aids. Concerns about child sexual abuse should always be shared with other professionals.

Physical inspection of the external genitalia is a useful adjunct in gathering evidence of sexual abuse. Since many sexually abused children may have “normal” examination, so one cannot rule out abuse by examination only. Perhaps the only way to prove absolutely that sexual abuse occurred is to find sperm inside a young girl’s vagina. All other examinations are to detect scars, abnormalities, and pathogens that are highly suggestive of sexual abuse. Although visual inspection by an experienced physician can detect nearly all abnormalities, the use of colposcopy has greatly advanced the understanding and teaching of sexual abuse. Newer refinements include stereoscopic photography and recording of the colposcopic examination on videotape.

Apart from signs of physical injury in the genital area, or diagnosis of sexually acquired disease, sexual abuse may be suspected if the child shows one or more of the following—sexually seductive behavior, sexual knowledge inappropriate for his or her age, severe psychosomatic symptoms, especially nonepileptic seizures, severe acting-out behavior, especially running away, sexually precocious behavior, self-injurious or self-destructive behavior in the absence of other apparent stress, pregnancy in the early teen years.

Emotional Abuse

Emotional abuse is likely to be most evident when members are seen together as a unit. It will be noted that one or both of parents is openly critical of the child, with constant sarcasm and hostile comments. Parents should be seen separately to establish the reasons for such negative attitudes, and partly to determine whether they are suffering from any form of mental illness. Children over the age of 7 or 8 years should, with parental consent, also be seen alone. After sometime spent in discussion of neutral topics, they can be asked about parental behavior. In children of school age, the teacher may be a valuable source of information.

Neglect

To diagnose neglect requires the efforts of a multidisciplinary team. Most cases of neglect require some assessment as to whether and why minimum parenting goals have or have not been achieved. Results for the child, not the intents of the caregiver, are the ultimate criterion.

The child is likely to present to the family doctor or in the accident and emergency department for reasons other

than neglect, but to be noted to be poorly clothed, dirty, and failing to thrive. A dietary history may reveal the child is receiving an inadequate calorie intake and there will be catch-up growth in hospital when an adequate nutritional intake is provided. There will be poor weight gain in relation to height. Psychological investigation will reveal developmental retardation, often global, but possibly confined to language. There may be signs of other forms of abuse also.

A home visit will reveal low standards of cleanliness and inadequate protection and safeguards against accidents. There may be an absence of books, toys, and other play material.

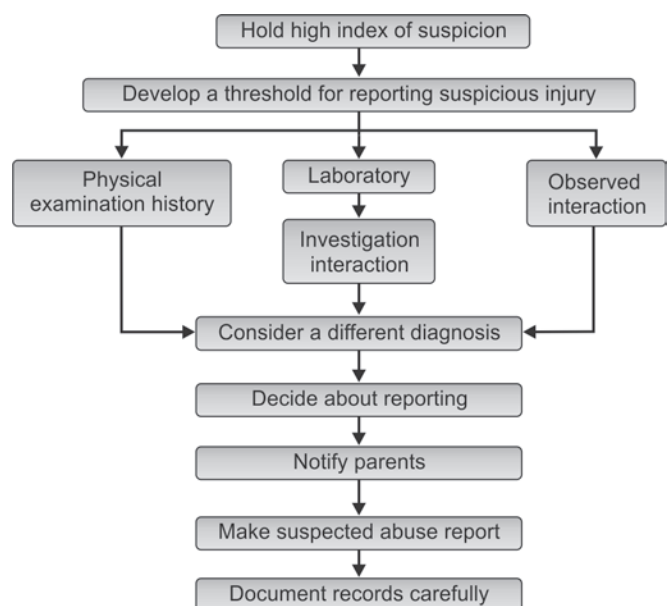

INTERVENTION

The management of established abuse is guided by three aims. The first is to prevent further abuse. The second is to mitigate the effects of what has already happened. The third is to meet the child’s emotional, social, and educational needs in the longer term, which may include deciding whether it is best for the child to live in their own family, making special educational provision and providing positive social experiences outside the home. Given the combination of factors that contribute to the development of child abuse, it seems clear that effective treatment must include multiple components (Flow chart 2).

Child and Parent Treatment

- Focus should be on multidimensional aspects of child abuse, rather than first in the abusive parent.
- Facilitating a more secure attachment between child and parent.

Flow chart 2: Steps in the management of child abuse

- Family-based therapy needs to improve the parent's developed self-image, reverse distortions of their child, interpret any link between the current abuse and the patient's own abuse history, and provide the parent with a positive model of raising children.
- Psychotherapy of the child should include creating a therapeutic environment, either in individual or group settings, which allow the child to master the trauma.
- Play therapy is useful in treatment of traumatized child.
- Pharmacotherapy can also improve the outcome of abused children, especially if they are manifesting symptoms of PTSD.

Propranolol, clonidine, guanfacine have been found to be effective in alleviating some symptoms like hyper-vigilance, hyperarousal and sleep disturbances, etc. Individual child and parental vulnerability, family dysfunction, and environmental stress variable all need to be addressed if the treatment is to be successful.

PREVENTION

Many approaches to the prevention of child abuse have been proposed, but the effectiveness of many of them has not been established by rigorous studies. Three types of child maltreatment primary prevention strategies are currently used. The first is competency enhancement, such as parent education programs. The second is preventing the onset of maltreating behaviors through, for instance, media campaigns, crisis hotlines, and community socialization programs for parents. The third is the targeting of high-risk groups, such as single, adolescent, parents of low socioeconomic status and those with complicated pregnancies and deliveries, to attend programs that increase parent-child contact and provide family support, such as visiting nurses or home visiting parent aides.

Educational efforts can play a great role as preventive approach to the problem of abuse. Also attention to social influences such as poverty, stress, and social isolation would be expected to reduce the development and perpetuation of abuse in the children.

CONCLUSION

Efforts directed at understanding, preventing, and interviewing in the area of child abuse remain at an early stage. In addition to the need to advocate for the improvement of environmental stressors, we urgently require the cessation of exposure of children to family violence, improved parenting, and child development education for parents and children. Child abuse is a multifaceted personal, familial, community, and societal phenomenon. At community level we require better welfare programs, legislation and administrative actions to curb this menace. The position can be further improved by the increased

cooperation between professionals and volunteers within the community, thus ensuring a much wider and comprehensive network of preventive, supportive and treatment options. Only with this multidisciplinary model we can ensure about the safety of our children.

Adolescent Health Problems

Rajesh Mehta, Neena Raina, Gaurav Shah

ADOLESCENCE

The term adolescence derives from the Latin word, 'adolescere' meaning "to grow, to mature" and is defined globally as the period from 10 to 19 years of age (WHO/ UN definitions: Adolescents 10–19 years; Youth 15–24 years; Young People 10–24 years). This phase in human life is marked by a plethora of growth and developmental changes in the physical, mental, sexual and psychosocial domains. These changes are universal and conform usually to a predictable sequence and pattern, although there are variations in the velocity of growth and development between girls and boys and from person to person. Adolescents constitute about one-fifth of world's population and about 22 percent in the South-East Asia (SEA) region. Adolescents are full of life and energy and are an important asset for national development. Adolescence phase is full of opportunities as it is vulnerable to several risks, many of these related to health.

Adolescents are generally perceived to be healthy since the mortality in this age group is relatively low. However, adolescents do have health issues that have implications that are immediate as well as for later life. It is indeed crucial that society invests in keeping adolescents healthy so that they grow to their maximum potential and contribute to economic growth and development of the country. Preventing health problems among adolescents and responding to health problems as and when these arise deserves to be a priority for health sector. It is important to understand the main health problems during adolescence and their causative mechanisms in order to design appropriate services for adolescents.

ADOLESCENT HEALTH PROBLEMS

The problems faced by adolescents can be categorized in several ways. The problems can be mild in nature and

some of these are serious and may have life long consequences.

GENERAL HEALTH PROBLEMS AMONG ADOLESCENTS

The rapid physical and psychological changes in adolescents are accompanied by increased sensitivity and attention to bodily symptoms. Adolescents report some common symptoms that may not represent serious physical illness. Symptoms like headache, abdominal pain, backache, general weakness and vague body aches may reflect the anxiety due to the changes that the adolescent are going through. However, frequent headaches can also be a manifestation of depression in adolescents. Poor posture, during the phase of rapid height gain and in girls when they develop breasts, can also be a cause of backache. Poor dietary habits and choices can lead to accentuation or development of anemia that may be the cause of feeling of weakness or tiredness.

Many times these non-specific symptoms are used by adolescents to seek attention of parents and physicians since they find it difficult to communicate their actual concerns (like menstrual problems, concerns about nocturnal emission, delay in development of facial hair, sexual abuse, etc.). The physicians need to have the skills to build rapport, make the adolescent clients comfortable and seek out their actual underlying concerns. Timely recognition of the actual health concerns of the adolescents is important to address these in time for prevention of further risk behaviors and serious consequences.

PROBLEMS THAT ORIGINATE IN CHILDHOOD AND IMPACT HEALTH DURING ADOLESCENCE

- Adolescents/young people who survive repeated cycles of infections like diarrheal and respiratory diseases fail

to attain full adult growth and stature. Girls who do not achieve their full growth potential are at a greater risk of having complications during pregnancy and childbirth and give birth to low-birth-weight babies.

- Chronic under-nutrition during childhood, over and above the compromised fetal growth (low birth weight prevalence being about 30%) can result in stunted growth. Undernourished adolescents who become pregnant are further predisposed to malnutrition and micronutrient deficiencies. These factors can contribute to under-nutrition and health problems throughout the reproductive years giving birth to low birth weight babies thus completing an inter-generational vicious cycle of malnutrition.
- Perinatal asphyxia and infections of the central nervous system during neonatal period and childhood can lead to sequels like disorders of sight, hearing or speech that have a huge impact during adolescence. These affect not only performance but also self-esteem and personality of the adolescents.
- Neglect and differential access to food and care during infancy and childhood, child marriage, physical and sexual abuse can seriously affect the physical, mental and social well-being during adolescence.
- Diseases that start manifesting during childhood like thalassemia, juvenile diabetes, nephrotic syndrome, rheumatoid arthritis and epilepsy may continue during adolescence with additional psychosocial overlay and sometimes even worsening of the symptoms.

HEALTH PROBLEMS ORIGINATING DURING ADOLESCENCE WITH LIFELONG CONSEQUENCES

- Increased nutritional requirements put adolescents at the risk of under-nutrition and anemia that are likely to have life long consequences including compromised reproductive health outcomes for girls. On the under hand, excessive use of junk food that is rich in calories and fats along with decreased physical activity can lead to overweight and obesity that continues during adult life.
- Use of tobacco, alcohol, and other drugs and harmful substances many times starts during adolescence with substantial adverse effects like chronic lung or liver disease, and cancer manifest during adulthood or later. Most cases of addiction among adults actually start during adolescence.
- Use of alcohol and drugs impairs judgment and increases the risk-taking behavior of adolescents/young people like over-speeding and dangerous driving leading to accidental injury, violence and unprotected sexual relations. All of these may have health implications that are life long.
- Unsafe/unprotected sexual relations can cause unwanted pregnancy and sexually transmitted infections including HIV infection among adolescents/young people. Such infections and unwanted pregnancy and unsafe abortion with associated reproductive health risks can have serious consequences during adolescence as well as in later life. Adolescent pregnancy is associated with higher maternal, perinatal, neonatal and infant mortality. There are social implications of adolescent pregnancy on girls, especially in case of out of wedlock pregnancy, like interruption of schooling and truncated economic opportunities in addition to social rejection.
- Prevailing gender norms in many societies often lead to a lower status of women with a relative lack of physical, social and economic power. This makes adolescent girls and young women particularly vulnerable, among others, to (a) physical violence; (b) economically-coerced sex; (c) abuse at the workplace; and (d) trafficking and prostitution. This can be severely detrimental to their physical and mental health that continues life long.

Common Adolescent Health Problems

- *Pubertal health concerns and problems:* Anxiety and stress related to growing up issues; early and delayed puberty; musculo-skeletal conditions like kyphosis and scoliosis of spine; gynecological conditions like menstrual disorders, polycystic ovarian disorder syndrome, vaginal discharge; skin and hair conditions like acne, hair loss and hirsutism. Concerns about physical appearance are quite common.
- *Sexual health concerns and problems:* Concerns about sexual attraction and urge, nocturnal ejaculation, masturbation, premature ejaculation, sexual orientation and unsafe sexual engagement, STIs/HIV; sexual coercion and abuse
- *Reproductive health problems:* Early pregnancy (largely related to early marriage of girls) and childbirth related problems like increased risk of complications, higher maternal, neonatal and infant mortality, abortion related problems
- *Nutritional problems:* Under-nutrition, micronutrient deficiencies and anemia, eating disorders, overweight and obesity
- *Mental health problems:* Stress, anxiety, depression, obsessive and compulsive disorders, suicide, behavioral disorders
- *Substance use:* Tobacco, alcohol, drugs
- *Injuries and violence:* Sports injuries, road traffic injuries, burns, drowning, violence
- *Infectious diseases* that are not specific to this age like tuberculosis, malaria, kala azar

ADOLESCENT BEHAVIORS UNDERLIE THE HEALTH PROBLEMS

Many, if not all health problems in adolescents are behavior related. The critical adolescent behaviors and lifestyles that are related with health risks are:

- *Eating behavior:* What foods they prefer and eating patterns determines their nutrition status. Typical behavior of meal missing can lead to under nutrition and indulgence in junk food makes them prone to overweight and obesity.
- *Physical activity:* Low physical activity on account excessive TV watching, computer and video gaming puts them at risk of overweight and obesity.
- Unsafe sexual behavior makes them vulnerable to unwanted pregnancy and STIs, HIV/AIDS
- Use of tobacco, alcohol and drugs exposes them to several health risks in addition to social and medical consequences.
- Thrill seeking behavior like fast driving, heroism on play field, etc. makes them prone to injuries.

Clustering of Adolescent Behaviors and Health Problems

The adolescent health problems are inter-related and clustering is common. The adolescents who start using tobacco early are also known to initiate sexual engagement early. As mentioned earlier use of alcohol and drugs is associated with impaired judgment and makes them prone to take risks like fast driving leading to accidents and indulging in unsafe sex leading to unwanted pregnancy, unsafe abortion and STIs/HIV. Additionally, adolescent behaviors and health problems are determined by several underlying factors or determinants.

DETERMINANTS OF ADOLESCENT BEHAVIORS

The adolescent behaviors that underlie the adolescent health problems, in turn depend on intermediate and underlying factors called determinants. In the multi-factorial web there are well recognized “risk factors” for adolescent health and development. These are:

- *Psychosocial risk factors:* Lack of social support, isolation, low self-confidence, low self-esteem, high self-blame, misdirected peer pressure in absence of adequate knowledge, low learning ability, social dependence, cultural rootlessness or cultural confusion, lack of recreational, creative and working opportunities
- *Adolescent body image concerns:* Poor body image (how the adolescents perceive various features of their bodies) may be at the root of many “unexplained” behaviors and symptoms. The symptoms of poor body image may range from “stomach-ache”, headaches, and panic-attacks to menstrual disorders, anorexia and smoking (to lose weight!). The self-perception that a girl is overweight (even though her weight is

normal for her height) is the predominant reason for dieting and visits to the slimming centers rather than any actual increase in weight. Sometimes high-risk sexual behavior (to prove that one is attractive enough to the other gender, desire to prove physical strength and sexual powers) also arises due to body image concerns.

- *Physiological/biological risk factors:* Physiological immaturity of tissues (cervical and vaginal epithelium that increases vulnerability to contract STIs/HIV), endocrinal and other physiological changes
- *Behavioral risk factors:* Smoking, alcohol misuse, unhealthy eating habits, unsafe sex, substance use, thrill seeking, criminal/illegal activities
- *Situation/condition risk factors:* Poverty, low education/occupation, illiteracy, ignorance about sex and sexuality, stress, inadequate housing facilities, migration, discrimination due to sex, race, etc.

Role of Social Environment

Health-enhancing behavior and outcomes are primarily the responsibility of adolescents themselves. However, the knowledge, skills and opportunities they need to make healthy choices and to develop are influenced by the larger social, political, economic, and cultural context in which they grow and change. The key areas in the social environment include:

- *Relationships with the family and other adults:* Evidence¹ has shown that adolescents who have positive relationships (connectedness) with their parents and other adults (e.g. teachers) are less likely to initiate sex too early, less likely to use drugs and alcohol, and less likely to experience depression.
- *Influence of friends and peer groups:* Peer group has a special influence on adolescents. Friends are considered more important than parents and siblings at this age. Peer influence can be both positive, like in academics and sports, etc. as well as negative like substance use, over speeding, and unsafe sexual behavior.
- *Societal attitudes and norms:* Societal norms that value adolescents, their health and development will promote the healthy development of adolescents. On the other hand, social norms that value early marriage among adolescent girls, for example, serve as negative influences on their health outcomes as well as educational and economic opportunities.
- *Policies and legislation:* Policies and legislation that support adolescent health and development are very likely to significantly influence the healthy development of adolescents. For example, a reproductive health policy that allows adolescents, regardless of their marital status, to access contraceptive services,

¹ Broadening the horizon: Balancing protection and risk for adolescents, Geneva, World Health Organization, 2001.

will enable adolescents to protect themselves from early, unwanted pregnancies and sexually transmitted infections. Similarly legislation for safety while driving (use of helmet, seat belts) and restriction on tobacco selling and usage near the educational institution have a health promoting effect.

- *Mass media and entertainment:* The media can promote adolescent health and development by (1) providing accurate information on health and development issues; (2) communicating and mobilizing community support for promoting adolescent health and development; (3) giving space to positive role models and achievements of adolescents and young people, and (4) addressing aspects of the social environment and policies that have a negative impact on adolescent health and development. Access to and widespread use of social media like facebook, internet, email, etc. has become very popular among adolescents and young people and can be used to reach out to them.
- *Gender considerations in adolescent health and development:* Gender, as a concept, is used to describe those characteristics and roles of boys/men and girls/women, which are socially constructed in contrast to those, which are biologically determined. Thus, a gender approach places emphasis on the role of social factors in health. Adolescent boys are treated differently from adolescent girls. In most societies, boys are preferred to girls, and given more attention, opportunities and resources like less food and less care when they are sick and have less access to education and training that would enable them to improve their situation. It also leads to early marriage (and early motherhood) for girls. Their subordinate roles in relationships with men often means that they are not in a position to demand safe sex practices that would protect them from contracting the infections. Their lower social status and relative lack of physical, social and economic power often makes them more vulnerable, among others, to physical violence, sexual harassment, economically-coerced sex; abuse at the work place, and forced prostitution. On the other hand boys are more prone to morbidity and mortality due to injuries, accidents and violence because of the social expectations that they would indulge in outdoor activities much more than girls.

This understanding of multi-factorial determination of adolescent health and development is important to realize that many sectors have to contribute to prevention of adolescent health problems in collaboration with the health sector.

HEALTH SITUATION OF ADOLESCENTS IN THE SOUTH-EAST ASIA REGION

Based on the recent national demographic and health surveys (DHS) in the countries of the region the following picture emerges (graphics are provided at Annexure 1):

- *Mortality rates* among adolescents in the SEA region are generally lower than those observed in children or in older age groups. Globally, 97 percent of deaths among 10 to 24 year olds in 2004 occurred in low-income and middle-income countries, almost two-third of these in Sub-Saharan Africa and South-East Asia. In South-East Asia maternal causes of death (hemorrhage, sepsis, abortion complications) account for a higher proportion of deaths among females. Among males, injury-related deaths (traffic accidents, violence, fire-related injuries and drowning) account for a high proportion of deaths.²
- *Under-nutrition and anemia* are a public health concern in the adolescent age group in the region. Low BMI (<18.5) is reported from 24 percent (Maldives) to 47 percent (India) and anemia is prevalent in more than 50 percent of adolescents in several countries of the region. On the other hand, prevalence of overweight (BMI >25) among adolescents is gradually increasing, being 8 percent in Sri Lanka, 15 percent in Timor-Leste and 24 percent in Maldives.
- *Early childbearing* is a public health priority in several SEAR countries. Early pregnancy has higher chances of adverse reproductive health outcomes like high maternal mortality ratio and infant mortality rate. Adolescent women are two to five times more likely to die due to causes related to pregnancy and childbirth as compared to women in their twenties. Neonatal and infant mortality rates are higher among women aged <20 than among 20 to 29 year olds.

Considering that adolescent fertility remains high in some countries and is associated with higher maternal as well as infant mortality, this age group is significantly responsible for contributing to population momentum and a high MMR and IMR in the region.

- *Unmet needs for contraception* in married adolescents are high in Nepal, Maldives and India, with higher rates in women aged 15-19 than their older counterparts.
- *HIV prevalence among youth* (15–24 years) ranges from 0.01 to 1.32 percent; more than one-third of new HIV infections are reported in the age group 15-24 years.
- In many countries, prevalence of STIs is high in young people. In Bangladesh, more than 50 percent of the patients who sought treatment at formal facilities were young people. In Thailand, new STI cases reported among students have increased from 3 percent in 2000 to 10 percent by 2004.

² Global patterns of mortality in young people: a systematic analysis of population health data; George C Patton, Carolyn Coffey, Susan M Sawyer, Russell M Viner, Dagmar M Haller, Krishna Bose, Theo Vos, Jane Ferguson, Colin D Mathers; Lancet 2009;374:881–92.

Behaviors of Adolescents

- *Initiation of sexual activity* among adolescents could be as early as 13 years in some adolescents (Thailand 2004). Early sexual activity exposes adolescents to the risks of STIs and HIV in addition to the risk of unintended pregnancy.
- About 95 percent of new HIV infections in young people in Asia are in young sex workers, young men who have sex with men (MSMs) and young injecting drug users (IDUs). In Myanmar almost 53 percent of female sex workers aged 15-19 years were HIV positive in 2006. Of the total reported AIDS cases among IDUs in Indonesia, more than 40 percent were in the 15-24 year age groups.
- *Low condom use* characterizes a vast majority of sexual encounters among adolescents in the region. Condom use by sexually active male secondary students in Thailand with female sex workers was found to be 43 percent while it was less than 40 percent for all other partner types as well. In India, Bangladesh, Nepal and Sri Lanka not more than 52 percent of young males used condoms at the last high risk sex.
- *Drug and substance abuse* among adolescents is an emerging problem. The global youth tobacco survey (2003) showed a high prevalence of tobacco use in young people in SEAR. Injecting drug use among adolescents and young people has also increased in the region. In Maldives, the maximum number of cases of drug abuse was found in the age group of 16-24 years. In Nepal, half of the 50,000 injecting drug users were between 16 and 25 years.

Knowledge of Sexual and Reproductive Health Issues among Adolescents

- *The knowledge of contraceptives* among adolescents is high in the region, exceeding 90 percent among married adolescent females in almost all the countries but the contraceptive use rate is very low indeed.
- Though most young people have heard of HIV/AIDS, comprehensive knowledge of transmission and prevention is low and misconceptions are widespread. In India, 84.9 percent of youth had heard of HIV/AIDS, but only half of them were aware of two correct methods of prevention. In Myanmar, more than 90 percent of youth have heard of HIV/AIDS however only 18 percent of young women and 25 percent of young men knew two methods of HIV prevention. In Maldives, 34 percent of youth were not aware that a healthy-looking person could be HIV positive.
- *Awareness of STIs* and its symptoms is also generally low. In Sri Lanka 58 percent, in India 29 percent and in Timor-Leste 4 percent of adolescents were aware of STIs. Most young people do not perceive the risk for STIs and HIV.

- *Awareness of risk does not necessarily translate into safe behaviors.* In Indonesia, though 88 percent of young men were aware of condoms for HIV prevention, only 15 percent used a condom at the last commercial sex encounter. In India, 52 percent reported using a condom at the last casual sex while only 34 percent reported consistent condom use with all partners, despite quite high awareness about this preventive method. In Nepal, more than 90 percent youth knew where to get condoms, less than 10 percent used it with any partner. (DHS data from these countries)

IMPLICATIONS OF ADOLESCENT HEALTH SITUATION

Many of the health problems of adolescents described above are behavior dependent and are interrelated. Sexual behavior and gender relations, use of substances, dealing with conflicts and risks often have common roots. Preventive interventions for these behaviors are the same. Such interventions ensure positive personal growth and development. Healthy development of adolescents underlies prevention of adolescent health problems. Fortunately, the positive adolescent behaviors as well as the protective factors are also common and can be reinforced to keep the adolescents healthy and protected from health risks.

Provision of a safe and supportive environment that ensures sustained inputs for healthy and full development of adolescents is crucial. Several players in society like parents, families, teachers, society at large, and governments must contribute towards this.

A number of ministries and departments—health, education, social welfare, law and justice, etc.—need to work together and with civil society (including adolescents and their families) and community-based organizations to address the needs and problems of adolescents. The Ministry of Health must assume a central role for developing and sustaining a multi-sectoral response to promote adolescent health and development (Box 1).

National Response to Adolescent Health in South-East Asia Region

Although services, providers trained in reproductive health and HIV/AIDS and supplies may be available in the countries, adolescents and young people hesitate to use these services. At many places, the information and services needed by adolescents are not available or are not accessible. Health care providers have limited capacity to deal effectively and sensitively with adolescent clients. Biased and judgmental attitudes of providers, lack of privacy and confidentiality act as significant barriers to care-seeking behavior. Health care providers need capacity building to enable them to help a client who is 16 years and not six or 26 years old. The other common reasons for not using existing health services are lack of awareness,

Box 1: Why invest in adolescent health and development

Large number of adolescents: There are 1.2 billion adolescents worldwide; 350 million in South-East Asia; 1 in every 5 people in the world is an adolescent; 85 percent of adolescents live in developing countries.

Adolescents have been marginalized. They are generally considered healthy, thus there are very few programs for them.

Current health scenario (global situation)

- 300 million young people are smokers
- 16 million babies are born to adolescent girls each year (2008)
- There are about 2.6 million new HIV infections among young people per year (representing 50% of all new cases); 7000 young people are infected with HIV daily; about five young people are infected with HIV every minute
- There are more than 1,550,000 cases of tuberculosis each year among youth
- In addition to 100,000 suicides, there are 4 million suicide attempts by adolescents each year
- More than one million adolescents lose their lives—mostly through violence, pregnancy complications, and illnesses that are either preventable or treatable.

Impact on future health scenario

- Behavior formed in adolescence has implications for individual and public health. For example smoking in adolescence leads to 150 million tobacco-related deaths among adults, and early drinkers are four times more likely to develop alcohol dependency.
- *Economic reasons:* Healthy development of adolescents leads to improved productivity, and averts future health costs. Behaviors formed during adolescence have an impact on adult morbidity and mortality, which in turn has economic implications.

Human rights: Adolescents, through the Convention on the Rights of the Child have rights to a safe and supportive environment, information and skills, health services and counseling.

shyness or embarrassment, financial constraints, distance, and concern about the negative/unsympathetic attitude of health providers.

- A supportive policy environment is important to enhance access and coverage of the desired services for adolescents. Laws and policies in some countries remain indifferent to the sexual and reproductive health needs of adolescents. In some countries access to condoms, contraceptives, voluntary counseling and testing services and abortion services are restricted due to age (legally minors) and marital status. It is important to have clear policy guidelines within the existing legal framework to support access to services

by adolescents especially the ones below the legal age of consent. The national review of laws and policies for adolescent health review has been conducted Sri Lanka and Bangladesh, which revealed policy gaps that have been identified for advocacy with policy makers to redress the situation so that access by adolescents to the available services can be enhanced.

- Initial steps have been taken towards developing adolescent health programmes in several member countries in the region like India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka, Thailand and Timor Leste. However, national strategy on adolescent health has been developed only in Bangladesh, India, Indonesia, Myanmar, and Nepal. The main focus of programmes has been sexual and reproductive health, including HIV. Increased attention is needed to address unhealthy lifestyles, mental health and violence. One reason for inadequate attention to these issues may be that we do not have national level data on these.
- To improve the access for adolescent clients to services national standards for adolescent friendly health services have been developed in Bangladesh, India, Indonesia, Nepal, Thailand and Timor Leste.
- National adaptation of the global adolescent health training package has been carried out in several member states and they have started building capacity of the health care providers for delivering appropriate services in a sensitive and non-judgmental manner. Adolescent friendly health services are being rolled out in the countries in a phased manner.

India has done particularly well in institutionalizing adolescent friendly health services within the public health system under the National Rural Health Mission. Adolescent reproductive and sexual health strategy was launched in 2006 as one of the key technical strategies under the national reproductive and child health program (RCH II). All the thirty five states and union territories have planned various activities for operationalizing adolescent friendly health services at selected health facilities and through outreach services and school health programme. Capacity building package has been adapted from the WHO global packages.

In India, other Ministries are also contributing to adolescent health through several programs. Ministry of Women and Child Development has recently launched Rajiv Gandhi Scheme for empowering adolescent girls (Sabla scheme) under which nutrition supplementation, IFA supplementation, vocational skills building and reproductive health education. Education Ministry provides adolescent education programme in the schools to provide age appropriate health education and life skills development to class 9 and 11 students all over the country. Ministry of Youth and Sports has a countrywide programme to organize youth clubs that integrates cultural

activities, sports and health education for out of school adolescents/young people.

Professional associations like Indian Academy of Pediatrics and Federation of Gynecological Societies of India have worked closely with Ministry of Health to support Adolescent Reproductive and Sexual Health strategy under NHM/RCH-II. Their members in private sector are taking up the responsibility of offering friendly health services to adolescents as per the national standards.

However, much more needs to be done for ensuring coordination among various programmes in the government sector as well as collaboration with the private sector to reach out to maximum number of adolescents to keep them healthy.

SUMMARY

Twenty percent of world population belongs to 10-19 years age group (adolescents) who have a specific set of public health problems. The health of adolescents will determine whether the societies will ensure achieving their human potential for realizing the demographic bonus towards national development. Adolescents have to face a multitude of health problems like pubertal disorders and

concerns, nutritional problems, sexual and reproductive health problems, injuries and violence, mental health problems and substance use problems in addition to common communicable diseases that are endemic in the countries. Preventing these health problems and responding to the health problems through easily accessible adolescent friendly health services is an essential investment that health sector must undertake in order to ensure that adolescents/young people are able to contribute to the national development to their maximum potential. Countries need to develop a multi-sectoral response to promote adolescent health and development that underlies prevention of health problems.

Mental Health Issues in Adolescents

CP Bansal, S Yamuna

INTRODUCTION

Adolescents are in a transition between the dependency of childhood and the autonomy and independence of adulthood. This transition is brought on by the hormonal changes of puberty. Adolescence is a period of mood swings with certain prolonged periods of sadness or elation depending on the environment in which he or she lives. The psychosocial evolution of adolescents predisposes them to mental health challenges which may result in mental illnesses in a few adolescents.

Very young adolescents are closer to parents but late adolescents not only move away from parents in search of autonomy and independence, but they also become closer to their peer group such as friends or with their intimate partners as in a relationship. Issues affecting their feelings, emotions and mood are usually unmasked, expressed, shared or discussed only with the group of people with whom they are comfortable.

Knowledge about mental health presentations in adolescents is very poor in the community that most behaviors in adolescents are either perceived as “difficult behaviors” with parental disapproval and reprimand or pushed aside as being part of the “storm and stress” of adolescence and is usually not addressed as the features are considered as part of the growth and development of the individual. It is now understood that such difficult behaviors are not part of normative development and thus it is essential to help these boys and girls with appropriate intervention to ease out their psychological upheavals.

Help seeking behavior among adolescents is also low because the adolescents are ignorant about the subtle differences between wellness and illness; adolescents do not unmask their mental health concerns unless they are comfortable with the attitude of the health care provider; adolescents are cooperative only in an environment where there is maintenance of privacy and confidentiality.

Adolescents are comfortable to take help from the health care providers who are able to evince that kind of comfort and confidentiality. Thus it becomes the duty of the primary care provider to take a proactive role in detecting symptoms of mental illness in the adolescents who reach them for primary health care needs.

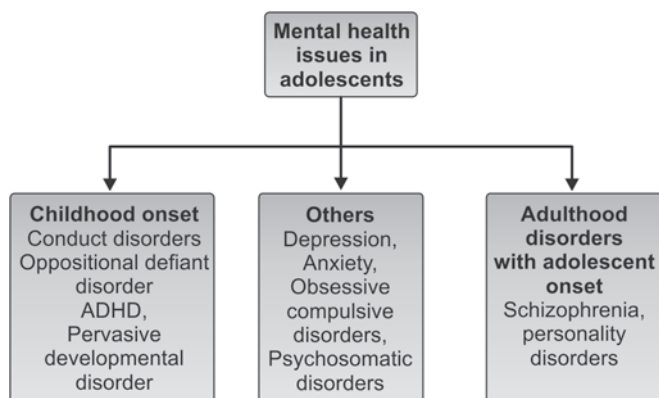

Depression in children and adolescents is associated with poor psychosocial functioning, high psychiatric comorbidity, and risk of recurrent episodes or onset of bipolar disorder. Depression during adolescence is associated with higher rates of smoking, alcohol abuse, unhealthy eating, and infrequent exercise and thus increasing the proneness of the adolescent to all lifestyle diseases. Thus depression during early adolescence has consequences for health and associated costs during young adulthood. Thus it is beneficial to inculcate the necessary skills to screen and treat depression among adolescents who reach us.

As pediatricians are well known to a growing child in view of familiarity, exploring the psychosocial aspects of the adolescents’ development through Home, education/employment, peer group activities, drugs, sexuality and suicide/depression (HEADSS) screening can be carried out with ease. If pediatricians can take the evaluation with an eye to detect difficulty in coping with the emotional demands of adolescence, early identification of mental health issues or illnesses would be feasible.

COMMON MENTAL HEALTH ISSUES IN ADOLESCENTS (FLOW CHART 1)

Mental Illnesses in adolescents can be classified as follows:

- Disorders of childhood may reach us during adolescence as they have not been addressed during childhood. Examples are conduct disorders, oppositional defiant disorders and attention deficit hyperkinetic

Flow chart 1: Common mental health issues in adolescents

disorders and pervasive developmental disorders which are not dealt with here.

- A few disorders can present during adolescence and thus contribute towards the morbidity and mortality of the adolescents. Depression, anxiety, obsessive compulsive disorders, psychosomatic disorders are a few disorders that deserve our active intervention during adolescence. If left untreated their course and prognosis can become troublesome at a later date.
- Disorders of mental health that happen in adults predominantly might have their onset during adolescence like schizophrenia, personality disorders etc. This group of disorders is also not dealt with here.

An attempt is being made to give an overview of the second class of disorders, their presentation, diagnosis and management in a way to stimulate the thoughts of the primary pediatrician:

- To recognize the manifestations of these illnesses from parents' account of their adolescents' behaviors
- To identify the conditions early during a casual interaction with an adolescent
- To spread messages in the community about the clinical features that should make parents, peers or teachers to suspect the illnesses in the adolescents they encounter
- To manage the illness with reasonable comfort until the help of a mental health professional is available.

With this objective in mind this chapter is aimed at addressing the common presenting features, clinical manifestations, diagnosis and early management of adolescent depression and anxiety disorders.

DEPRESSION IN ADOLESCENTS

Epidemiology of Depression in Adolescents

Prevalence of depression among adolescents is related to age, gender and social class. Very young adolescents have a lower prevalence and the number of adolescents with depression increases with age. Thus it ranges from

1 percent in very young adolescents to 25 percent among late teens depending on the other factors that increase the proneness to depression. Until the onset of puberty, depression among children is equally prevalent among boys and girls. With menarche girls are two to three times more likely to become depressed than boys. Depression is more common among lower socioeconomic status because of exposure to chronic environmental chaos and disquietness.

Families with members who have had depressive disorders have children who are more prone for depression during their lifetime. Though there is no definite cause for depression, biological factors, endocrine factors, social factors and structural factors in the brain seem to contribute to the features of depression. Environmental factors like socioeconomic status, level of family conflict, neglect or abuse, parental separation or divorce seem to play a significant role in the unfolding of depression in adolescents.

Major Depressive Disorder

It is easy to diagnose a major depressive disorder when it is acute in a child with no previous psychiatric illness. In children with anxiety disorders, or hyperactivity the onset can be insidious.

Clinical Features

Depression is characterized by the presence of the majority of the following symptoms for more than two weeks (DSM IV TR criteria). At least five of the following should be present associated with a change from the previous level of functioning:

- Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g. feels sad or empty or bored) or observation made by others (e.g. appears tearful). (In children and adolescents, this may be characterized as an irritable mood)
- Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (loss of interest to play or listen to music)
- Significant weight loss when not dieting or weight gain (e.g. a change of more than 5 percent of body weight in a month), or decrease or increase in appetite nearly every day
- Poor sleep/insomnia or excess sleep/hypersomnia nearly every day
- Psychomotor agitation or retardation nearly every day (Symptoms may take the form of restlessness, pacing, tapping fingers or feet, abruptly starting and stopping tasks, meaninglessly moving objects around, and more. Psychomotor agitation is frequently, though not exclusively, associated with agitated depression. Adolescents may be fidgeting their fingers frequently during consultation)

- Fatigue or loss of energy nearly every day
- Feelings of worthlessness or excessive or inappropriate guilt nearly every day
- Diminished ability to think or concentrate on academics, or indecisiveness, nearly every day
- Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).

The symptoms are not better accounted for by bereavement, i.e. after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

The clinical features of depression can also be classified as affective, behavioral, cognitive and somatic symptoms:

- Affective or mood symptoms include depressed mood and feelings of worthlessness or guilt
- Behavioral symptoms include social withdrawal and agitation
- Cognitive symptoms or problems in thinking include difficulty with concentration or making decisions
- Somatic or physical symptoms include insomnia or hypersomnia (sleeping too much).

In prepubertal children the depression presents with more somatic symptoms; affective and behavioral symptoms are more common among adolescents. Adolescents also have cognitive symptoms with difficulty in focusing/concentration. In adolescents frank antisocial behavior can occur as a presenting feature. Feelings of restlessness, grouching, boredom, aggression, sulkiness, reluctance to cooperate with family expectations, withdrawal from social activities and a desire to leave home are common in adolescent depression. School difficulties, inattention to grooming, increased sensitivity to rejection in romantic relationships also signify depression in adolescents.

Feeling sad, bored, empty, low, down, blue, unhappy, feel like crying for no reason, are some of the words that are used by children and adolescents to convey sadness. Functional impairment due to depression extends to all areas of functioning including scholastic performance, peer interactions, and family relationships. Inputs from peers, teachers and significant others would help in the diagnosis of depression in adolescents.

Highly intelligent academically strong children can compensate for the mood disorder with increased attention

to academics. It is common for most children to have a fall in grades when affected by depression. Difficulty in concentration, lack of interest, lack of motivation, fatigue, sleepiness, depressive ruminations contribute to the fall in grades.

If features of depression are associated with hallucinations and delusions psychosis should be considered.

Depression rarely presents as a single entity. It is usually accompanied by other coexisting mental illnesses. Conduct disorder, oppositional defiant disorder, panic disorder, attention deficit hyperkinetic disorder, anxiety disorders, disruptive disorders, and substance use disorders are the usual comorbid disorders among adolescents. It is essential to identify the comorbid conditions as these conditions either alter the presenting features of depression or prolong the recovery phase of depression. If the conditions are not taken care of, the recovery can be different from the expected course.

INVESTIGATIONS

No lab investigation can help in making a diagnosis of depressive disorder. But it may help us in identifying other disorders like hypothyroidism, anemia, etc.

DIFFERENTIAL DIAGNOSIS

- *Adjustment disorder*: Where the depressive features should follow within three months of a negative life event.
- *Attention deficit hyperkinetic disorder*: It is usually a comorbid condition where inattention, hyperactivity and impulsivity coexist
- *Specific learning disability*: It is also an accompanying disorder. Inability to excel in academics may be associated with dysphoria which can present as depression
- *Conduct disorder*: Here aggression to people and animals, destruction to property, theft and deceitfulness, serious violation of rules with significant impairment to social, personal and academic life. This also coexists in many adolescents
- *Oppositional defiant disorder*: It is usually confused with the externalizing behaviors of depressed adolescents. Negativistic, hostile and defiant behavior exists in the absence of sadness or guilt
- *Substance use disorder*: It is found that most adolescents with substance use are depressed. In most instances depressed adolescents resort to substance use to fight the low mood and seek ecstasy. As these moments of ecstasy are short lived the habit of using mind altering substances becomes a regular habit.

As all the conditions mentioned need a Psychiatrist to identify and differentiate, it is better that a Primary care provider takes the help of the psychiatrist in managing adolescents with features suggestive of depression.

TREATMENT

Hospitalization

The decision to admit an adolescent with depressive features arises in the event of suicidal ideation and plans. To maintain safety, hospitalization might be needed in helping the adolescent stay away from his impulsive self destructive behavior. If there is an associated substance use, admission would help in deaddiction.

Pharmacotherapy and Psychotherapy

Combination of cognitive behavior therapy (CBT) and selective serotonin reuptake inhibitors (SSRI) is observed to give better results than either of them given alone.

Cognitive behavior therapy aims to challenge the maladaptive beliefs and enhance problem solving abilities and social competence.

Pharmacological agents that are used in the treatment of childhood and adolescent depression are Fluoxetine (10 mg), Sertraline (25 mg), Citalopram (10 mg), Escitalopram (10 mg), and Fluvoxamine (25 to 50 mg) with starting doses in the brackets. Dose might have to be enhanced in adolescents.

Duration of Treatment

If there is good response to initiation of antidepressants, maintenance of treatment for 6 months followed by cessation of treatment when the stress levels are low are the recommendations for treating depressive disorder.

Course and Prognosis

Mean duration of depression in children and adolescents is 9 months, if left untreated but with a range of 3 to 250 weeks. Recurrence of symptoms of depression is common during adulthood in up to 40 percent within two years and in 70 percent in another five years.

Depressive disorders are usually associated with relationship difficulties. Poor academic achievement and persistently poor self esteem.

Dysthymic Disorder

Dysthymic disorder in children and adolescents consists of a depressed or irritable mood for most of the day, for more days than not, over a period of at least 1 year.

According to DSM IV TR diagnostic criteria at least three of the following symptoms must accompany the depressed or irritable mood:

- Poor self-esteem
- Pessimism or hopelessness
- Loss of interest
- Social withdrawal
- Chronic fatigue
- Feelings of guilt

- Brooding about the past
- Irritability or excessive anger
- Decreased activity or productivity
- Poor concentration or memory.

During the year of the disturbance, these symptoms do not resolve for more than 2 months at a time. Dysthymic disorder may be followed or may evolve into a major depressive disorder.

When minor depressive episodes follow a significant stressful life event by less than 3 months, it is often part of an adjustment disorder.

Anxiety Disorders

Like pain anxiety has protective functions for human survival. If a person develops anxiety in the presence of danger in the environment, anxiety serves a protective function. If anxiety is disproportionately high or if there is anxiety in the absence of danger it is considered pathological.

Anxiety in an appropriate amount helps in functioning. But an excessive anxiety that disturbs the social, physical and academic functioning of an adolescent is abnormal. Being anxious on the day of the examination or on the Valentine's day before proposing to their loved one is acceptable. But a devastating level of anxiety that prevents an adolescent from interacting with any one or makes the adolescent dread about school to avoid examination is pathological and need intervention.

There are many anxiety disorders and each of them has specific features but all of them are bound together by a common theme of excessive, irrational fear and dread.

Generalized Anxiety Disorder

Children and adolescents who exhibit excessive worries pertaining to their performance in school and social settings and experience at least one physiologic symptom such as restlessness, poor concentration, muscle tension or irritability related to their fears, may be diagnosed to have generalized anxiety disorder. Adolescents with generalised anxiety disorder feel fearful in multiple settings and expect and visualize negative outcomes when faced with social or academic challenges.

Social Phobia

Those adolescents who experience high levels of anxiety while in social situations that makes them avoid participation in social events meet the criteria for social phobia. They experience distress and discomfort in the presence of peers as well as adults. They have concerns about being humiliated, embarrassed or negatively judged.

In the above conditions the experience of adolescent can approach panic or terror. Adolescents may not directly express their worries but their behaviors often reflect their fears. They may refuse to go to school on the day of

examination or presentation, or to a friend's house. They may retreat from group activities and express feelings of loneliness because of their self-imposed isolation.

Sleep difficulties, night mares and morbid fears accompany anxiety disorders. They may have somatic symptoms including gastrointestinal symptoms, nausea, vomiting, stomach aches, and unexplained pains in various parts of the body. Older adolescents complain about palpitations, breathlessness, dizziness, faintness, and feelings of strangulation.

Investigation

No lab investigation can help in the diagnosis of anxiety disorder. But investigation may be necessary to rule out organic reasons for the somatic symptoms.

Adolescents who are able to continue normal functioning with respect to peer group interaction, school attendance and social situations have a better prognosis than those who confine themselves within the four walls of their room.

Treatment

Family education, family psychosocial intervention, CBT and pharmacologic interventions have to be considered while treating adolescents with anxiety disorders.

Obsessive Compulsive Disorder

Obsessive compulsive disorder is characterized by the presence of obsessions and compulsions. Obsessions are recurrent intrusive thoughts associated with anxiety or tension. Compulsions are repetitive purposeful mental or physical actions aimed at reducing fears and tensions caused by obsessions. Many candidates with OCD have their onset during childhood and adolescence. The presenting features are almost similar to that in adults but with one exception. The children and/or adolescents may not perceive their thoughts or behaviors as unreasonable.

The common obsessions in children and adolescents are dirt, germs, disease, followed by worries about harm befalling the family members or themselves. The typical compulsive behaviors are checking, cleaning, counting or arranging items in an order. Associated features are avoidance and delayed task completion.

The compulsive behaviors are carried out to keep the harmful effects from affecting self.

Treatment is a combination of SSRI and cognitive behavior therapy. Fluoxetine (20 to 60 mg), Fluvoxamine (up to 200 mg) and Sertraline (50 to 200 mg) have been approved for treating adolescents with OCD.

OCD is a waxing and waning disorder with a great variation in course and outcome. Almost 50 percent remit completely and another 25 percent have partial remission in a year's time.

Psychosomatic Disorders

All of us have certain expectations when we deal with patients who present with physical symptoms. We expect a reasonable degree of discomfort, we seek for certain pathological manifestations, we acknowledge a realistic amount of emotional and psychological distress to be associated with the physical symptom and we also expect a corresponding setback in day to day functioning of the person with the symptoms.

When the subjective symptoms do not correspond to the objective findings a mental health evaluation is usually considered. These are the disorders which can be referred to as psychosomatic disorders when symptoms such as choking, inability to breathe, hyperventilation, inability to write, paralysis, etc. present in the absence of clinical findings.

CONCLUSION

Early identification of mental health issues in adolescents would help the pediatricians in referring them to mental health professionals at an appropriate time. The pharmacological treatment is recommended for almost for 6 to 9 months duration. Family education and family support by primary care pediatrician to encourage continuous treatment offered by the psychiatrist would help the family in adhering to the treatment advised.

Parenting of Adolescents

Atul M Kanikar

INTRODUCTION

Parenting is perhaps the most important and possibly one of the most challenging developmental tasks of middle age. The influence of parental behaviors has produced lasting impact on the course of history of India. Right since the golden era of Indian history, legends and philosophers have been giving guidelines on effective ways of dealing with children for better individual and community outcome. Classical examples of family conflicts, parental neglect, extreme obedience as well as fatal adolescent rebelliousness are cited even in the great epics of *Ramayana* and *Mahabharata*. The best citations, however, come from “*Chanakya Niti*” by Kautilya, where situations of healthy milieu and disaster within the family along with the ideal changes in attitude of a parent when the child blooms into a teenager are described. Chanakya says, “A true son must be obedient to his father, a true father should look after his son, similarly true friend is one who is trustworthy and true wife is one who makes her husband happy.” Although not all the mythological and historical theories remain applicable today, the basic impact of various internal and external factors on the entire family dynamics must be considered when one deals with the issues of parenting.

WHAT IS PARENTING?

“There isn’t any formula or method. You learn to love by loving.”

Aldous Huxley

Parenting, by definition means an art of bringing up children. It is a bilateral process where both parents and children learn from each other mostly by their mistakes. This art is more learnt than inherited. The ways in which parental behaviors influence this process are called as parenting styles. Our own parents teach most of these methods to us. The hereditary pattern is commonly exhibited in methods employed in disciplining children. Thus, we see some families where spanking and yelling is very common. Others use words and nonverbal methods with possibly better outcome. External factors like educational background of the parents, sociocultural backgrounds, economic well-being, type of guests visiting the house, size of the family, mother’s profession (whether earning or a housewife) and her status in the family, methods of family enjoyment, grandparental interference, etc. also have a beneficial or harmful role to play.

Without going further into the nature against nurture issue, let us say that, the natural instincts, desires, and methods of parenting need to be upgraded with the current scientific technique, so as to produce a perfect blend both for parents and children. Parenting comprises of various tasks, emotions, responsibilities, difficulties and rewards involved in the process of bringing up children. It is an ongoing process and will remain so. However, the situation worsens in a parent’s middle age when the children enter the stressful adolescence and the grandparents face the aging disasters. The middle generation is thus sandwiched between these two highly sensitive generations.

The principal components of parenting are depicted in the Table 1.

Table 1: Components of parenting

<i>S. No.</i>	<i>Important parental task</i>	<i>Methods</i>
1.	Responding to the needs	Caring for children, spending time and energy for them.
2.	Establishing closeness	Hugging, giving a pat on the back, holding hands, etc.
3.	Helping to be independent	Giving household responsibilities with increasing grade, avoiding unnecessary interference for the tasks, which they can do independently.
4.	Accepting the individuality	Giving obvious respect to what a teenager has to say, consider teenager's point of view, involving them in family discussions, etc.
5.	Nurturing self-esteem	Avoid empty praise, criticizing too much, and have realistic expectations for what a teenager can do.
6.	Accepting our own limitations	Spending quality time together because everybody is busy, having realistic expectations from other family members, understanding the ever changing outside world and our own physical and economic constraints.

There is a significant difference in parenting a younger child and an adolescent. Even during adolescence the early phase, i.e. between 10 to 14 years, is described as the most difficult to handle phase by many parents mainly due to the rebellion shown by a teenager, which is most of the times unexpected. The parental anxiety as shown by strict disciplinary methods, extreme restrictions on the teenager, especially girls, is also at its peak owing to the fact that most parents are not prepared for the changes of menarche that occurs usually in early adolescence. A teenager is also very clumsy (due to disproportionate growth) in this period giving rise to many clashes with the family. A teenager is treated simultaneously as a child and an adult, which adds to further confusion.

As a parent (and a pediatrician too), it is mandatory to know the range of normal behavior and psychosocial development of both—an adolescent and a parent entering his/her middle age. Unless we learn about this universal process, the issue of parenting remains baseless. The developmental tasks of a teenager and the parents may individually or in combination contribute to the family environment, which has to be caring, nurturing and stable for the desired outcome. The art of understanding one another and one of the important life skills called “empathy” can be easily learnt if both parents and teenagers understand these universal changes depicted in the following charts.

The developmental tasks of teenage are given in the Table 2:

Table 2: Developmental tasks in teenage

<i>S. No.</i>	<i>Developmental task</i>	<i>Description in brief</i>	<i>Possible hazards</i>
1.	Hormonal effects leading to sexual maturation.	Adjustment to body and mind, establishing a sexual identity within the norms and values of family, friends and society.	Inferiority complex for late bloomers and awkwardness and risk of abuse/aggressive behavior for early bloomers.
2.	Abstract thinking skills.	Ability to think about ‘thinking’, constructing philosophies, creative thinking, and the intelligence is at its peak.	Moodiness, day dreaming, disturbed sleep and dietary habits, parents feel that something is wrong.
3.	Developing more complex level of perspective taking.	Understanding human relationships and a teenager can empathize with others.	If ignored, the teenager feels neglected leading to self-blame and depression.
4.	New coping skills in decision-making, problem solving, and conflict resolution.	A teenager can think about and plan for the future, can moderate their risk taking to serve goals rather than jeopardize them.	Disputes over issues like career, marriage, etc.
5.	Identify moral standards, values, and belief systems.	Self-analysis of personal values and beliefs rather than those emphasized from childhood by elders.	The concept of ‘generation gap’, and rebellious behaviors.
6.	Understand and express a set of complex emotional experiences.	Ability to identify and communicate more complex emotions, to understand other's emotions better, abstract thinking about emotions.	A teenager may attempt to behave and act like an adult, may become choosy about pet friends and family members.

Contd....

Contd....

7.	To cultivate friendships those are mutually close and supportive.	Shift from friendships based largely on the sharing of interests and activities to those based on sharing of ideas and feelings with more emphasis on nonverbal communication.	A teenager usually does not find an ideal friend/friends who can share mutual trust and understanding.
8.	To establish key aspects of identity.	It is an ability to identify self and its connection to valued people and group. Adolescents also need to develop a positive identity around gender, physical attributes, sexuality, culture and ethnicity.	Failure in these areas can have lifelong effects. Many disorders of adulthood have their roots in adolescence.
9.	To meet the demands of increasingly mature roles and responsibilities.	The list of expectations from the teenager by the family, peers and the society, is frustrating and unending.	Considerable stress.
10.	Renegotiate relationships with adults in parenting roles.	Inclination to separate from the family, along with a desire to be an important part of it simultaneously.	Conflicts over priorities, career, supercompetitions and comparisons.

It is quite obvious from the above chart that adolescence is a stressful and stormy period needing help, guidance and vigilance too by parents and caretakers. The need for parent education is thus very much obvious. However, the task is not all that easy. The common feedback obtained from various parenting workshops conducted over last three years in urban and semiurban middle class families, the principal issues of concern were a sense of unease while talking to children, gross ignorance for developmental tasks and parenting skills, severe time constraints for everybody in the family, uncertainty about teenagers willingness to listen, adolescent's rebel and

undisciplined behavior, external influences and career choices. Many parents tend to hide these concerns at least initially.

In spite of all these and many other hindrances, parents need to take active interest in adolescent's daily activities and keep a noninterfering vigil, failing which a teenager becomes vulnerable to peer pressure and other hazards like low actualization of potentials, underachievement, inadequate coping skills, feeling of inferiority, poor self concept and self-esteem, deviant/risk taking behavior and increased risk of psychosocial problems. The usual causes of family conflicts are depicted in Table 4.

The developmental tasks and main concerns of the middle age Table 3:

Table 3: Developmental tasks and main concerns in middle age

<i>S. No.</i>	<i>Developmental task and important issues</i>	<i>Brief description</i>	<i>Possible hazards</i>
1.	Advancing health restrictions	Decreased physical capacities and mental threshold. Emergence of various disease processes. Premenopausal changes.	Physical and financial stress. Fear of disability and untimely death.
2.	Significant change in various interests	Assuming civic and social responsibilities. Interests are more solitary in nature, e.g. reading, TV watching, etc.	Other family members may feel 'left-out'. Increased sexual desire in females and lessened interest in males.
3.	Tasks related to family life	Relating oneself to one's spouse as a person. Adjusting to aging parents. To provide guidance and economic support to growing children. Increased worries for career of children.	Series of conflicts and family frictions. "Empty nest syndrome" after the adolescents have left for vocational training.
4.	Vocational adjustments	Life after retirement, boredom, financial constraints, feeling of uselessness, self-blame for other family member's failures.	Depression and increased irritability.

Table 4: Causes of family conflict

<i>Adolescent causes</i>	<i>Parental causes</i>
Parents seem old fashioned and bad critics.	Authoritative style.
Unfair/childish disciplinary methods.	Middle age crisis.
Unhealthy sibling relationships.	Grandparents—interference/liability.
Comparisons with parents of peers.	Family triangle and favoritism.
Family gatherings are “boring”.	Expectation of a “dream child”.
Increased social activities.	“Empty nest” syndrome.
Tendency to experiment.	Self-blame and feeling of hopelessness.

Psychologists have described various styles of parental behaviors. The main categories are—authoritarian (“I am the boss, and everybody has to obey me”), permissive (full freedom and no restrictions), negligent (“leave them alone”), avoidant (“leave me alone”) and authoritative (sits across the table, negotiating type). Most parents use all these methods in combination, depending on the situation under consideration. However, the most frequently applied methods decide the type of parental personality. The teenagers also view their parents with these typical labels. As mentioned earlier, most of these styles are repeated through generations. The conflict arises when a parent has to change his/her style because of the changing world that is not within one’s control. Thus, we tend to blame the media, internet and peers for our own shortcomings.

The five principal parenting responsibilities are given in the Table 5:

Table 5: Parenting responsibilities

1. Unconditional love	Being on their side, no matter what. Separating the teenager and the misdeed. Not giving incentives, not bribing them for better results.
2. Keep a close vigil	Monitoring daily routine, knowing the whereabouts and peer group, encouraging group activities but with supervision, interaction with parents of peers, regular visits to the PTA.
3. Discipline	Maximum use of nonverbal communication, explaining family rules clearly, using time appropriate rewards and punishment in proper dose, maintaining consistency and uniformity.
4. Introspection	Parents need to be a good role model themselves; they should also accept a teenager’s as well as their own limitations.
5. Crossing the boundaries	Thinking beyond our own family, forming parent’s self-help groups, taking professional help if necessary.

SPECIFIC ISSUES IN PARENTING A TEENAGER

Discipline

The process of discipline involves a series of well-intended efforts by parents and caregivers to inculcate “the art of controlling oneself”. If properly learnt and consistently practiced, discipline becomes a very important foundation for the growth of children. It brings self-confidence, feeling of mastery over life and positive social experience for children even after growing as adults. The positive feelings themselves add up to bring out a well-behaved and confident parent of the future, who would in turn express positive discipline techniques successfully. The discipline process should act as “vaccination” against untoward effects of peers, media and other difficult to handle situations in life.

Discipline, by definition means, “to teach”. However, by tradition, we equate this with punishment. Discipline also is, encouraging children, guiding them and helping them feel good about themselves. The root word of discipline is disciple—a person who leads others in the way they should go. Discipline is not what you do to the child, but what you do with and for the child, may it be a toddler or a teenager. The short-term goal of discipline is to guide everyday behavior and to protect children from hurting themselves and others, however, the long-term goal should be to bring out a confident, self-disciplined individual, responsible for his/her own behavior, is relying upon self and is comfortable and happy about it.

There are only one/two children per family now, and all parents wish to give the best to their children, there is no another chance. Nobody wants to accept that quite naturally, according to normal distribution probability curve, every child cannot be at the top. What we are giving to our children is a “filtered” parenting (I keep the troubles with me; my children should never face problems). In addition, we have working parents who unnecessarily feel guilty for not giving time to their children, but at the same time want their children to win the ever-increasing competitions, may it be studies, sports or debating.

Sibling Rivalry

Constant fighting, putting downs, arguing and comparisons among children are the causes of sheer frustrations and concern for most parents. Brothers and sisters often use their fights to gain parental attention and to show power. Some bickering is considered as normal but creating dangerous situations and physical fighting are definitely not. It is the most common complaint from the grandparents.

The ignorance as to how to handle the rivalry adds to the anger and helplessness of parents who adopt the age old method of spanking and yelling which worsens the situation. The interference by other family members, e.g. grandparents and favoritism makes it more difficult for

the parents to chalk out resolving strategies. When parents react to hostility with hostility, they are unwittingly promoting sibling rivalry. Research has proved beyond doubt that siblings set up their own private verbal and nonverbal language between themselves that marks their unique relationships. Amongst siblings, the negative behaviors and approaches are also mutually agreed to some extent, ruling out the need for frequent interference by caretakers. Another interesting research finding is that often the younger sibling provokes a negative reaction from the older one and probably knew no other way to grab attention of the older sibling. Provocation is thought to be the best way of initiating contact.

It is the primary duty of the parents to inculcate healthy sibling relationships without punishment and humiliation. Following guidelines may help right from the arrival of the second child.

- Allow children to express their feelings towards each other. Parents should acknowledge the child's feelings first, e.g. anger or frustration, understand their emotions and feelings and let them know that, e.g. "you sound furious! you wish he could have asked you before using your things" or "would you like to draw a picture of how mad you feel". Surprisingly, the anger melts away quickly, when children know that parents know and understand their anger.
- Avoid comparisons as far as possible. The grandparents, relatives and even visitors have this constant habit of comparing children, that too in front of them. No two children are similar, and why should they be? Comparing does not ensure better behaviors. In fact, it increases the jealousy and envy. Praising one child in the presence of another also should be avoided for the same reason.
- Parents should treat their children individually, not equally. One strategy effective for one child may not be so for the other one.
- Never take sides. Parents cannot resist the urge to figure out who started the fight. It is wrong to punish the older or stronger each time. Instead of taking sides, express your comment on the overall behavior.
- Let the children work it out for themselves. Stay out of minor fights. Step in only when children cannot work out the solutions.
- Teach children some better ways of getting attention. This is especially important for the younger sibling. The older child should be asked to use respectful words and praise to strengthen the new method of initiation. Giving children shared responsibilities and taking turns may also work.
- Family gatherings and family meals offer a great opportunity to understand another person's feelings.
- If possible, separate space (corners in the room) should be provided to each child. Putting time limits on the use of common devices like telephone, television, etc.

and dividing age appropriate chores equally also helps in avoiding conflicts. Rules and consequences should be made extremely clear to everybody in the house.

- Counseling and physical examination to rule out neurological disorder remain the last methods for managing intractable and serious physical fights among siblings.

All sibling relationships are not frictional at least not all the times. Consequently, sibling relationships are important aids to the young child's personal and social development. Older sibs serve as role models to imitate and young children discover what is expected from them. From these quarrels, children learn what other children will and will not tolerate, learn how to be good losers as well as gracious winners.

During adolescence, older siblings often criticize the appearance and behavior of the younger child, who in turn likes to tease and bully even younger siblings. If parents try to interfere, they are accused of playing favorites. The children may gang up against the parents and the 'pet' sibling. Moreover, rivalries in adolescence have a more lasting effect in future relationships than those in early childhood.

Grandparents Role

There are more advantages than disadvantages of having grandparents in the family. It all depends on everybody's personalities, expectations, contributions, and communication styles. Often parents and grandparents get into a situation where they are competing at 'parenting'. The smaller issues like disciplining, menu for lunch, TV watching, birthday gifts, dressing styles, doing chores, etc. soon become the topics of disputes. The previous confrontations are remembered and bounced back and conflicts set in. Whatever may be the causes of disputes in between the elders, care should be taken that, the solutions are sought early, the memories do not last long, and the children do not take advantage of the situations. Conflicts within the families are known for ages, it is the unfavorable influences of the outside world that create the constant need for healthy family relationships. Because what the family cannot provide, teenagers will try to recover it from outside world, which will never give the warmth and comfort of a home. Grandparents can and should provide their comfortable lap; one can climb onto to listen to the best stories and useful advices, may it be grandchildren or the parents themselves.

Schools and Colleges

The academic performance of a child and teenager is directly proportional to the parental interests and interactions with school activities irrespective of the financial and educational status of the parents. Both parents should regularly attend the parent teacher association programs

and take part in all the school activities meant for parents. These visits help the parents to know about new activities and opportunities at school, the sustained interests of the teenager, and other issues like peer influence and school violence, etc. The teaching staff also feels more concerned and responsible for the betterment of the pupil. Parents should follow these guidelines as far as possible:

- Reserving at least 15 to 20 minute discussion time for school activities shows that the parents are taking active interest in academics and that education is important to them.
- Helping children and young adolescents in homework and reading with them.
- Setting limits for TV watching and computer games. A well made timetable that is well followed, by everyone in the family is most of the times sufficient.
- Monitoring out of school activities of the teenager helps to prevent future serious consequences.
- In recent times, the coaching classes have dominated the educational world of teenagers. This system breaks the parents financially and students mentally and physically asking for special nutritional needs during entrance examinations. Parents should see that the teenager is not dragged in this distressing routine just because of peer pressure and as far as possible ensure that the school authorities themselves take steps to finish the curriculum well before the examination dates with ample revision sessions. Moreover, in case of failures or poor performance, the teenager should not be blamed in proportion to the money spent.

Boosting Self-Confidence

Teenagers whose parents say, “You can do it” are more likely to respond saying, “Yes, I can and I should”. This can be accomplished by encouraging new experiences since adolescents themselves love to develop new skills, teaching them a wide variety of basic skills including household work (even cooking), dividing a complicated task into portions within reach, giving proper reinforcement and appreciation (remember nonverbal communication) and telling them that mistakes are bound to be there and we learn to walk by stumbling.

Parents need to identify and nurture the natural abilities of the teenager that may be unique. Giving a supportive environment and positive remarks helps these skills to flourish. It also gives a feeling of respect and responsibilities. The final step is to honestly praise the teenager for actual accomplishments in a specific and unexaggerated manner. Association of what a teenager’s desire, with the after effects teaches them to be responsible. For example, if a teenager invites friends, he/she must do most of the cleaning after the party is over. Thus, a parent has done a great job if the teenager starts thinking about what might happen before he/she embarks on a course of action.

Alternatively, parents who treat a teenager like a young child may really end up with one.

Talking Together

With very busy schedules for the entire family, nowadays the parents and a teenager hardly get time to interact. Phone calls, scribbled messages and even e-mails have replaced or (?) eased the communication within families. The moodiness of adolescents and various burdens of parents further cause hindrances. Having at least one family meal together, planning a mutually suitable time, or just turning off the television may help provided there are no conflicting discussions. Family matters, emotional issues, the future, the past memories of parents, current events, personal interests, friends, etc. are the preferred topics for teenagers. The conversation has to be open with equal opportunities for both and at no moment parents should jump to preaching and pleading. Adolescents are capable of making informed choices provided they are allowed to choose. Many teenagers find difficulties in expressing anger, guilt, anxiety and grief. Parents must help and encourage teenagers to ventilate these disturbing feelings. It is all during these casual but useful conversations that parents can imbibe the ways to healthy lifestyles, honesty, courage, self-discipline and one’s commitment to the family. All these sessions go a long way in preventing serious problems in future.

The above technique needs lot of practice and patience at least initially. Parents should remember that in a given situation the teenagers should not be treated like criminals in the court and focusing on the past and putting labels has to be strictly avoided. Everyone in the family including grandparents should participate in the discussion but the ‘moderator’ must be the parents. In most of the routine matters these strategies really work. Everybody feels respected and responsible.

Occasionally there are far more serious situations. For example, a teenager gives way to peer pressure and lands up with drug addiction or an adolescent girl gets morning sickness. Following are some helpful tips for parents for facing these unfortunate but not so uncommon family calamities. Parents must offer unconditional love, whatever is the situation at hand.

Problem solving

State the problem as seen.

Open the discussion showing empathy.

List the possible solutions together.

Veto the unacceptable options.

Evaluate the remaining solutions.

Do the most acceptable to all.

- Parents may show that they understand the situation by saying, “I know, there are plenty of opportunities these days”
- In a firm voice one can mention that as a parent you will never allow anything to hurt the teenager.
- Help should be offered in the best possible way and the problem should be viewed together. Professional help may be taken if necessary.
- Accusation, putting labels and self-blame has to be avoided.
- Further follow-up and encouragement for improved behavior is a must.

Every responsible parent must be aware of certain warning signs in the teenager which may point out high risk behavior. Most of these behaviors are reversible, if picked up early. The mother can be the best clinician at home. Some of these signs include scholastic deterioration, disturbed sleep and appetite, disproportionate irritability, loss of interest in sports and recreational activities, a new set of (senior) friends, stealing money or valuables, avoiding hug and eye contact by parents and antisocial behavior.

Thus, wise parenting is the one that slowly shifts responsibilities, family values and social customs from parents to adolescents with a scope for further improvisations

that are for the betterment of the individual, family and society. There is nothing like an ideal child and a perfect parent. It is never too late to start taking interests and initiatives in adolescent care. The more one learns about it, the more one feels comfortable with a teenager and self. Moreover, the adolescent feels comfortable and confides best in parents for personal issues, thus fulfilling the important criteria of a successful parent. The untoward effects of the media and peers can thus be avoided, if parents can provide themselves as good role models. Teenage problems and parental worries are inevitable today. Running away from the battle will surely not help. Understanding the mechanisms and basics and preparing for the difficulties surely will.

Red Eye in Children

Anasua Ganguly, Vinay Kumar S, Himanshu Shekhar, Rajesh Sinha, Amit Khosla

INTRODUCTION

Red eye is the most common and nonspecific ocular sign presenting in emergency and outpatient departments. It is the most common ocular problem seen by primary care physicians.¹ Data from Middle East show that red eye accounts for approximately 15 percent of consultations with ophthalmologists and almost 6 percent with general medical practitioners.² Red eye from the patient perspective signifies visible appearance of abnormal redness of the globe, lids or adnexal structures.³ The clinical term 'red eye' is applied to a variety of infectious and inflammatory conditions involving one or more of ocular tissues including conjunctiva, cornea, lids and internal ocular structures. Conjunctivitis is the most common cause of red eye.¹

Signs and symptoms of red eye include redness, discharge, itching, pain, photophobia and changes in vision. Although most cases can be effectively managed in a primary care setting, a thorough understanding of the disease process is essential in recognizing danger signs that require ophthalmologic referral.

DANGER SIGNS

Danger signs point towards a more serious ocular condition including uveitis, keratitis, corneal abrasion, ulcer, glaucoma and thus necessitate a thorough evaluation and treatment by a trained ophthalmologist. The danger signs are:

- Severe pain
- Decreased visual acuity
- Photophobia (intolerance to light)
- Ciliary flush (redness in the immediate area around the circumference of the conjunctival corneal border—the limbus)
- Corneal opacification
- Pupil sluggishly reacting or not reacting to light

- Proptosis (outward bulging of the eyeball)
- Reduced ocular movements
- Raised intraocular pressure
- Immunocompromised host
- Worsening signs or no improvement despite therapy for 3 days.

CAUSES OF A RED EYE

Disorders Primarily of the Globe

Extraocular

- Conjunctiva
 - Conjunctivitis (and keratitis when mechanism is same)
 - Infectious—viral, bacterial, fungal
 - Allergic and hypersensitivity reactions
 - a. Acute
 - Seasonal allergic conjunctivitis
 - Perennial allergic conjunctivitis
 - b. Chronic
 - Vernal keratoconjunctivitis (VKC)
 - Atopic keratoconjunctivitis (AKC)
 - Giant papillary conjunctivitis
 - Phlyctenular conjunctivitis
 - Contact dermatitis/conjunctivitis
 - Toxic reactions
 - a. Chemical exposure
 - b. Topical medications and preservatives
 - Mechanical/irritant
 - a. Contact lens related
 - b. Foreign body
 - c. Trauma—child abuse, injury
 - d. Exposed sutures, glaucoma drainage device
 - Noninflammatory conjunctival redness
 - Subconjunctival hemorrhage

- Abnormal vascular engorgement—polycythemia vera
- Cornea
 - Corneal abrasion
 - Keratitis and corneal ulcer
 - Dry eye syndrome
 - Exposure keratoconjunctivitis
 - Paralytic (Bells palsy)
 - Nocturnal
 - Abnormal lid anatomy with inadequate closure
 - a. Congenital
 - b. Postsurgical
 - Neurotrophic keratoconjunctivitis
- Episclera/Sclera
 - Episcleritis
 - Scleritis

Intraocular

- Infectious or inflammatory
 - Congenital glaucoma
 - Uveitis
 - Anterior
 - Intermediate
 - Endophthalmitis
- Neoplastic
 - Any primary or metastatic malignant tumor (example retinoblastoma)
 - Masquerade syndrome

Disorders of the Eyelids and/or adnexal Structures

Eyelids

- Blepharitis
- Hordeolum
- Chalazion.

Orbital/Periorbital Structures

- Preseptal and orbital cellulitis
- Ruptured dermoid cyst
- Sinus mucocele
- Neoplastic
 - Malignant—primary, metastatic
 - Abnormal vascular engorgement
 - Arteriovenous malformations
 - Carotid cavernous fistula
 - Orbital varix

Nasolacrimal System

- Canaliculitis
- Dacrocystitis
- Nasolacrimal duct obstruction (NLDO) with secondary conjunctivitis
- Lacrimal gland
 - Dacryoadenitis

- Malignancy

Systemic Disorders Associated with Red Eye

- Stevens Johnson syndrome (SJS)
- Kawasaki disease
- Juvenile rheumatoid arthritis (JRA)
- Inflammatory bowel disease (IBD)
- Vitamin A deficiency
- Varicella, mumps, and measles
- Psoriasis
- Behcet disease
- Syphilis
- Tuberculosis.

APPROACH TO A CASE OF RED EYE

An accurate history with a thorough ocular and systemic examination provides the key to correct diagnosis in a case of red eye.

History Taking

In a child, a careful history taken from a reliable informant provides important background information for clinical examination. Questions to ask in the patient history include symptoms of the patient with onset and duration. Patient is specifically asked about pain, itching, discharge, decreased vision, intolerance to light and other danger signs which necessitate prompt referral to an ophthalmologist. The patient is enquired about:

- Any recurrent or seasonal occurrence of the symptoms
- Previous treatment received especially any over the counter medicines
- Any history of contact lens use
- Any preceding history of trauma or upper respiratory tract infection (indicating towards viral etiology of red eye)
- Any family history of hay fever, allergic rhinitis, asthma, atopic dermatitis that may point towards an allergic etiology of red eye
- History of any associated systemic illness like joint pain in JRA, abdominal pain, diarrhea in IBD.

Specific Clues to Etiology of Red Eye from History

Many associated symptoms of red eye are nonspecific. However, certain associations strongly suggest a particular diagnosis Flow chart 1.

- *Itching*: The pathognomonic symptom of ocular allergy is itching.⁴ Mild itching may also be associated with blepharitis, dry eye and occasionally infective conjunctivitis.¹
- *Discharge*: The type and amount of ocular discharge should be enquired. A serous discharge is most commonly associated with viral or allergic ocular conditions. A mucoid (stringy or ropy) discharge is

characteristic of allergy or dry eyes. A mucopurulent or purulent discharge with associated morning crusting and difficulty in opening the eye lids is suggestive of bacterial infection. Chlamydial disease tends to have mucopurulent discharge. Copious purulent discharge in first 3 to 5 days of life should raise suspicion of gonococcal conjunctivitis.⁵

Characteristics of discharge associated with red eye:

Etiology	Serous	Mucoid	Mucopurulent	Purulent
Viral	+	-	-	-
Allergic	+	+	-	-
Bacterial	-	-	+	+
Chlamydia	-	+	+	-
Neisseria	-	-	-	+
Dry eye	+	+	-	-

- *Unilateral or bilateral presentation:* Allergic conjunctivitis usually presents bilaterally. Infections caused by viruses and bacteria (including *Chlamydia*) initially present in one eye due to direct contact of eye with microbe, but the other eye gets involved soon after. Iritis, herpes, corneal abrasions, keratitis are usually unilateral.

General Survey

A detailed systemic examination indicates towards the etiology and systemic association of the red eye. Face examination may reveal herpes labialis in a case of herpetic conjunctivitis. Lymph node examination may reveal palpable preauricular and submandibular lymph node in viral or chlamydial conjunctivitis, toxic conjunctivitis secondary to topical medication. Palpable lymph nodes are rare in bacterial conjunctivitis except in hyperacute conjunctivitis caused by *Neisseria* species.¹

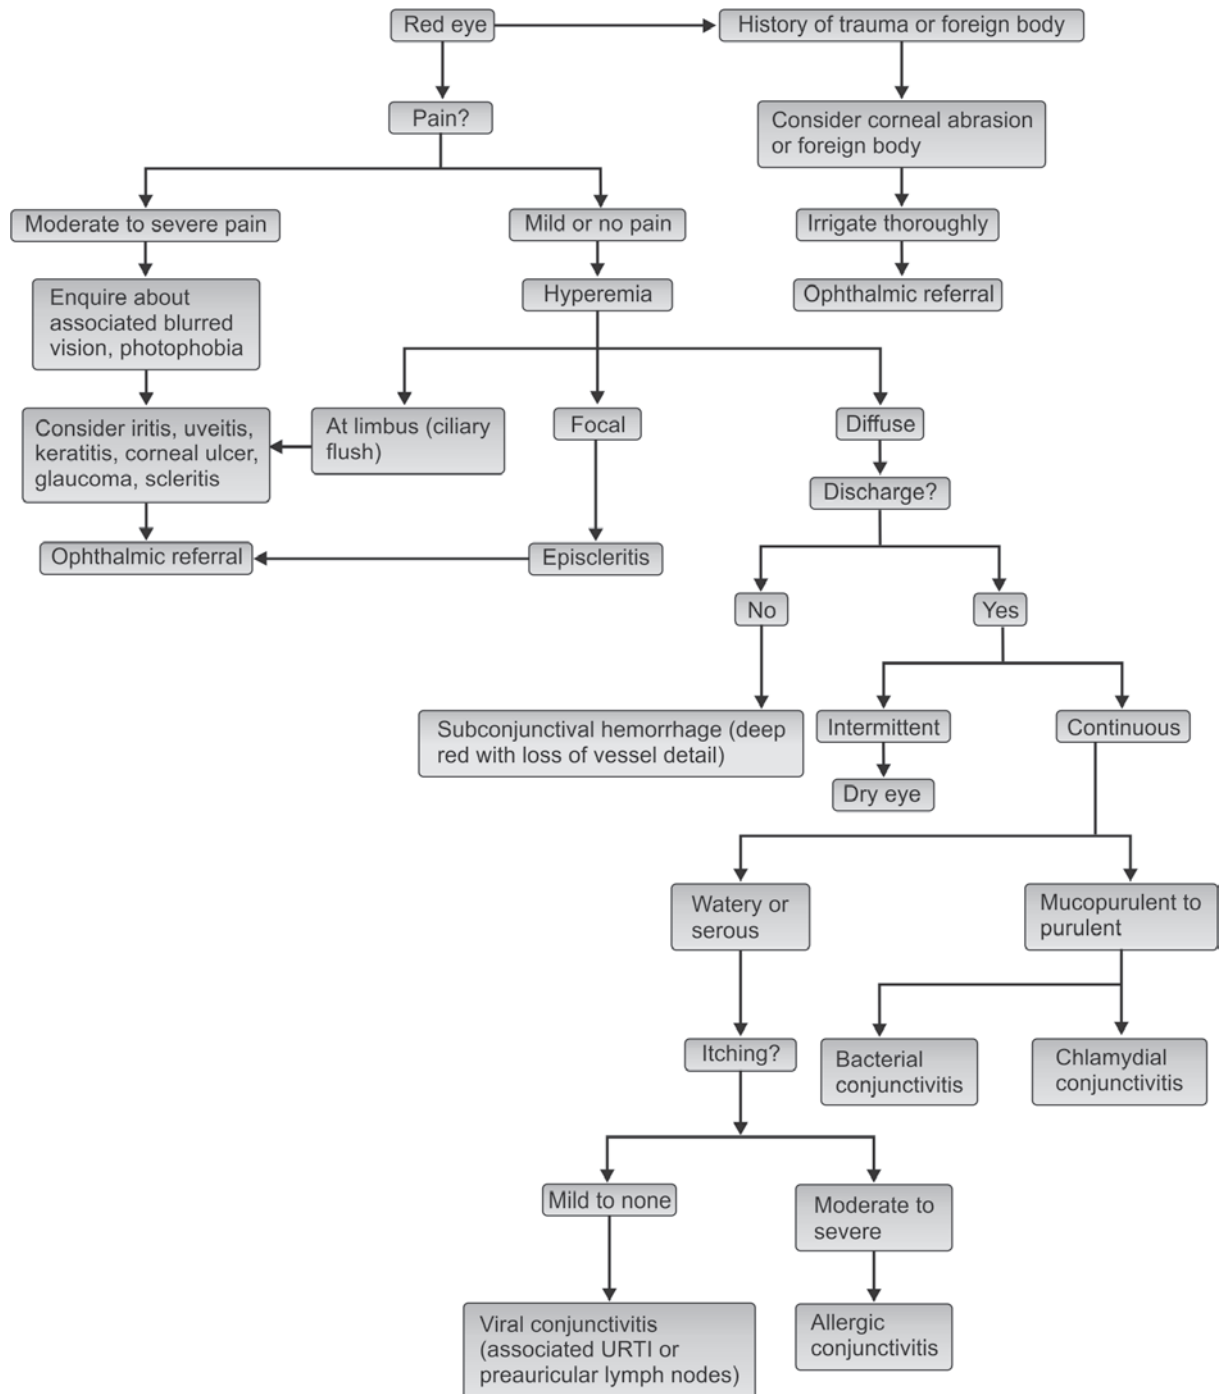

Ocular Examination

Examination of the red eye should be performed after contact lens or glasses (if child is wearing any) are removed. Examination is best done by using a slit lamp biomicroscope and a direct ophthalmoscope. In their absence, a magnifying instrument along with a pen light is very useful. A close look at the different external tissues of the eye individually provides essential information for etiological diagnosis of the red eye. Ocular examination includes:

- *Visual acuity:* Visual acuity of each eye is checked individually on the snellen chart with and without spectacles. Visual acuity usually remains unaffected in conjunctivitis unless there is an associated keratitis as in AKC, keratitis, uveitis, congenital glaucoma, episcleritis, scleritis all pose a serious threat to vision and require referral.⁶

- *Eyelid and adnexal structures:* Eyelids and eye lashes are examined for erythema and thickening of eyelid margins and crusting at the base of the eye lashes (blepharitis, dermatitis), periorbital discoloration (allergic shiners),⁷ blepharospasm (inability to keep eyes open) and ptosis. Eyelids may become swollen after exposure to an allergen or after insect bites.
- *Lid eversion:* Both the upper and the lower lids are everted to look for papillae or follicles. Presence of these reflects the chronicity of the conjunctival inflammatory response.⁷ Follicles are greyish, clear or yellow bumps that vary in size from pinpoint to 2 mm in diameter. They are usually associated with viral and chlamydial infections and have conjunctival vessels on surface. Papillae are cone shaped elevations on the conjunctiva, each containing a small tuft of blood vessels.⁸ Papillae are usually seen in chronic allergic disease.
- *Conjunctiva:* The conjunctiva is examined for chemosis (swelling), hyperemia, palpebral and bulbar papillae or follicles and any debris or obvious mucus in the tear film. The nature and amount of discharge is noted.
- *Location of redness:* In order to differentiate conjunctivitis from more serious forms of ocular inflammation the location of the redness is important. Diffuse conjunctival redness is most likely conjunctivitis. Circumciliary congestion (around the circumference of conjunctival-corneal border) indicates intraocular inflammation due to uveitis, endophthalmitis or raised intraocular pressure.⁵ Intraocular inflammation will more likely be associated with pain and globe tenderness but no discharge except tearing whereas in conjunctivitis there is discharge but no pain. Localized area of redness on conjunctiva may be related to a foreign body, trauma, episcleritis or scleritis. Deep red areas over conjunctiva with loss of vessel detail represent subconjunctival hemorrhage from trauma or a vascular maneuver.
- *Cornea:* The cornea should be perfectly smooth and transparent. Any greyish or milky white areas may indicate corneal ulcer. Mucus plaques adhering to cornea or conjunctiva are pathologic (dry eye, conjunctivitis). Discrete swellings with small white dots at the limbus (Horner Trantas dots) are commonly associated with chronic forms of conjunctivitis like AKC, VKC.
- *Anterior segment:* Iris appearance, anterior chamber reaction (cells or flare), are checked (anterior uveitis). Pupillary reactions are noted.
- *Ocular motility:* Limited ocular motility in eyes with painful red swollen eyelids point towards orbital cellulitis.
- *Intraocular pressure measurement (IOP):* Perkin's hand held tonometer can be used to measure IOP in children. In cooperative children Goldmann applanation tonometry can be done on a slit lamp. Raised IOP is seen in congenital glaucoma, secondary glaucoma due to uveitis or trauma.

Flow chart 1: Diagnostic algorithm for red eye

- *Posterior segment:* Posterior segment examination reveals vitreous exudates in intermediate uveitis and endophthalmitis. Optic disk evaluation is to be done for congenital glaucoma.

CONJUNCTIVITIS

The conjunctiva is a thin, translucent membrane that has a bulbar and a palpebral part. The bulbar part covers the white part of the eye ball (the sclera), and the palpebral part covers the inner surface of the eyelid. The term conjunctivitis refers to a broad group of conditions presenting as inflammation of the conjunctiva. Conjunctivitis is the most common cause of red eye.

Etiology: Conjunctival inflammation may be the result of infection or allergy or toxic reaction.

Common etiology of conjunctivitis by age:⁵

Age groups	Common etiology
Neonates <24 hours	Chemical conjunctivitis (silver nitrate)
<1 week	<i>Neisseria gonorrhoeae</i>
<1–2 weeks	<i>Chlamydia trachomatis</i>
Infants and toddlers—without otitis media	<i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> <i>Branhamella catarrhalis</i>
with otitis media	<i>Haemophilus influenzae</i>
School age children 1–5 years	HSV, varicella zoster
School age children and adolescents	Viral conjunctivitis Allergic conjunctivitis

Signs and symptoms: Signs and symptoms are similar with each of these etiologies. The redness of conjunctivitis spares the limbus. Ocular pain, photophobia, and decreased vision are not usually seen in conjunctivitis (with the exception of adenoviral keratoconjunctivitis). Itching and foreign body sensations are more likely due to allergic causes. Allergic or viral etiologies are associated with clear or mucoid discharge whereas purulent discharge suggests bacterial etiology. Preauricular lymphadenopathy and pharyngitis is suggestive of a viral etiology. There is no consensus as to whether bacterial or viral conjunctivitis is more common in pediatric age group. Weiss et al⁹ in 1993, Teoh et al⁵ in 2003 and Granet⁶ in 2008 have pointed bacterial conjunctivitis as the most likely cause of acute conjunctivitis in children. Whereas Sethuraman et al¹⁰ in 2009 and Seth et al¹¹ in 2011 have reported the incidence of viral conjunctivitis to be higher than that of bacterial conjunctivitis.

Bacterial Conjunctivitis

Patients with bacterial conjunctivitis present with red eye with mucopurulent discharge (Fig. 1) which causes eyelash matting and eye lid closure on waking up in the morning. This typical history and the presence of mucoid or purulent

Fig. 1: Bacterial conjunctivitis (For color version see plate 20)

discharge on examination are highly predictive of bacterial conjunctivitis.¹² It is most commonly spread through direct contact with contaminated fingers. Bacterial conjunctivitis is classified as hyperacute, acute or chronic based on duration and severity of clinical manifestations.^{13,14}

- Acute bacterial conjunctivitis is the most common form of bacterial conjunctivitis in primary care setting.¹³ It typically has an abrupt onset with tearing and ocular irritation developing in one eye initially but spreads to the opposite eye within 48 hours. Mucopurulent or purulent discharge develops within one or two days. Symptoms persist usually for less than four weeks. Examination reveals diffuse hyperemia of the bulbar and palpebral conjunctiva. *Haemophilus influenzae* is the most commonly isolated organism followed by *Streptococcus pneumoniae* and *Staphylococcus aureus*.¹² *Treatment:* In most cases diagnosis is based on clinical findings. Laboratory studies are performed only in severe cases and those unresponsive to initial treatment¹ to identify the organism and determine its sensitivity to antibiotic agents. Treatment consists of a broad spectrum topical antibiotic like fluoroquinolones (Ciprofloxacin 0.3%, Gatifloxacin 0.3%, moxifloxacin 0.5%) used three to four times per day. This empirical approach is highly effective and adverse consequences are rare.^{15,16}
- Chronic bacterial conjunctivitis is the most commonly caused by *Staphylococcus* species.¹ It usually develops in association with blepharitis and meibomian gland inflammation. Examination reveals flaky debris, erythema and warmth along the lid margin, eyelash loss and bulbar conjunctival hyperemia. Some patients also have recurrent styes and chalazion. Treatment includes establishment of good eyelid hygiene using warm compress and eyelid margin massage and application of appropriate topical antimicrobials.
- Hyperacute bacterial conjunctivitis is often associated with *Neisseria gonorrhoeae* in neonates, sexually active

adolescent. The infection has an abrupt onset, with rapid progression leading to corneal perforation. It is characterized by copious purulent discharge, pain, decreased vision. In neonates it typically presents in first three to five days of life.^{17,18}

Treatment includes hospitalization and adequate eye irrigation and administration of ceftriaxone 25 to 50 mg/kg intravenously or intramuscularly in a single dose. Conjunctival scrapings should be sent for culture and gram stain.⁵

Chlamydial Conjunctivitis

The most common organism causing ophthalmia neonatorum is *Chlamydia trachomatis*.¹⁷ Infants get exposed to *Chlamydia trachomatis* from mothers infected cervix during vaginal delivery. The incubation of *Chlamydia* is typically 1 week.⁶ Presentation is with mild to moderate hyperemia and discharge which can be scant, mucoid or copious purulent.

Treatment is with oral erythromycin 50 mg/kg/day divided into four daily doses for 10 to 14 days.

Viral Conjunctivitis

- *Adenoviral conjunctivitis*

Most viral conjunctivitis is caused by Adenovirus.⁵ It is usually a self-limiting disease and produces a follicular reaction. All forms of adenoviral conjunctivitis are extremely contagious. Transmission of infection occurs through direct contact with infected persons, contaminated instruments, swimming pool water or personal items.¹³

- *Pharyngoconjunctival fever*

Adenovirus types 3, 4 and 7 cause pharyngoconjunctival fever. Typically associated features are fever, pharyngitis, preauricular adenopathy. It is self-limiting and symptoms resolve between four days to two weeks.⁵⁻¹⁰

- *Epidemic keratoconjunctivitis*

Adenovirus serotypes 8, 19 and 37 are most commonly responsible for epidemic keratoconjunctivitis. It mostly affects older children. Symptoms include severe discomfort, photophobia, early follicular or late papillary reactions and small petechial hemorrhages. Many patients develop keratitis with subepithelial stromal infiltrates 7 to 10 days after onset of conjunctivitis.¹⁰

- *Acute hemorrhagic conjunctivitis*

Acute hemorrhagic conjunctivitis is most commonly caused by picorna viruses such as enterovirus and coxsackie virus and can also be caused by adenovirus type 11. It is also highly contagious and occurs in epidemics.¹⁹

- *Herpes virus conjunctivitis*

Herpes simplex virus conjunctivitis may occur with primary infection or with recurrence. Primary infection usually occurs between 1 and 5 years.²⁰ Recurrent

infections occur in adults. Ocular infections are mostly due to HSV-1 except in neonates in whom HSV-2 is more prevalent. Transmission of virus occurs through direct contact. Associated findings helping in diagnosis are lid vesicle, upper respiratory tract infection, gingivostomatitis, preauricular lymphadenopathy. Eighty percent cases of HIV conjunctivitis are unilateral.⁵ Corneal involvement with classic dendrites occurs in 50 percent of patients.

Conjunctiva can be affected by varicella zoster virus by primary or secondary infection. Conjunctivitis usually occurs in primary varicella (chicken pox) but corneal involvement is rare. Secondary infection occurs in distribution of ophthalmic division of the trigeminal nerve and is known as herpes zoster ophthalmicus. Corneal involvement and iritis are common.

Molluscum contagiosum can cause chronic follicular conjunctivitis and corneal changes (fine epithelial keratitis) in children causing red eye.²¹

Treatment: Primary treatment is patient education. Children should be kept away from the school until there is no discharge and to be advised not to share clothes, utensils. Treatment for viral conjunctivitis is supportive. Cold compress, artificial tears and topical vasoconstrictors may provide some relief. Topical steroids should be avoided as they have side effects and may aggravate the condition. Topical antibiotics are usually unnecessary as secondary bacterial infections are rare.⁵ For herpetic keratoconjunctivitis the topical medications that are used are trifluridine, idoxuridine or vidarabine.²² Oral acyclovir can be used in severe or recurrent lesions. Acyclovir resistant varicella zoster virus is treated with foscarnet.

Allergic Conjunctivitis

Allergic conjunctivitis is a group of diseases affecting the ocular surface associated with type 1 hypersensitivity reactions. It can be classified into acute diseases including seasonal and perennial allergic conjunctivitis and chronic diseases include vernal keratoconjunctivitis, atopic keratoconjunctivitis, and giant papillary conjunctivitis. Thus, the spectrum of conjunctivitis ranges from acute IgE mast cell mediated disorders (seasonal and perennial allergic conjunctivitis) to mixture of lymphocyte-mast cell-eosinophil mediated disorders (vernal keratoconjunctivitis, atopic keratoconjunctivitis) to predominantly lymphocyte mediated disorders (giant papillary conjunctivitis).⁷

Seasonal and Perennial Allergic Conjunctivitis

Seasonal and perennial allergic conjunctivitis accounts for 98 percent of patients with ocular allergy whereas AKC and VKC accounts for only 2 percent of all ocular allergies.⁴ Direct exposure of the ocular mucosal surfaces to environmental allergens most commonly grass and tree

pollen in seasonal allergic conjunctivitis and dust mites and animal dander in perennial allergic conjunctivitis⁶ causes cross linkage of membrane bound IgE which triggers mast cell degranulation releasing histamine, the primary contributor for the development of seasonal allergic conjunctivitis. Associated history of seasonal rhinitis is often present in these patients. Family history of atopy is present in around 70 percent of patients with seasonal allergic conjunctivitis.²³ Hay fever, asthma, atopic dermatitis are considered major atopies and idiopathic urticaria, nonhereditary angioedema, food allergies are considered minor atopies.

Patient complains of typical symptoms of ocular itch, watering, sneezing. On clinical examination conjunctival chemosis may be present although subtle and thus only visible on slit lamp biomicroscopy. Diagnosis is mainly clinical. Laboratory testing may be done to quantitatively estimate serum IgE level and for skin testing for hypersensitivity to allergens.

Treatment includes environmental control, cold compress, artificial tears and topical vasoconstriction. These cases are ideally treated with combination of antihistamine-mast cell stabilizers that are the newer antiallergic agents.⁴ (like olopatadine 0.1 percent, ketotifen 0.025%, azelastine 0.05% and epinastine 0.05%). Desensitization immunotherapy also has role in the treatment.

Vernal Keratoconjunctivitis

Vernal keratoconjunctivitis is a chronic bilateral disease of childhood with greater prevalence in males living in warm climates. It is an allergic conjunctival inflammatory disorder with an associated secondary keratopathy. It tends to burn out by the age of 30.²⁴

Symptoms are profound itching, redness, ropy discharge, tearing and severe photophobia. Tarsal VKC is characterized by classic hallmark of giant papillae in the upper tarsal conjunctiva leading to Cobblestone appearance (Fig.

Fig. 2: Giant papillary conjunctivitis with cobblestone appearance (For color version see plate 20)

2). In *Limbal VKC* large papillae are seen in conjunctiva at the corneoscleral limbus with collections of inflammatory cells rich in eosinophils at the apices of the limbal papillae called Horner-Trantas dots (Fig. 3).²³ The other signs include ropy lardaceous mucus thread in inferior fornix, an extra lower eyelid crease (Dennie Line),⁷ localized lipid deposition in anterior stroma of cornea resembling a small segment of arcus (Pseudogerontoxon)²⁵ pseudomembrane formation of the upper lid when everted and exposed to heat (Maxwell-Lyon sign), keratopathy which typically begins as diffuse superficial keratitis and afterwards form a frank trophic epithelial defect known as Shield Ulcer (Fig. 4).

Treatment: It includes cold compress, artificial tears, antihistaminic agents and mast cell stabilisers. Topical corticosteroid is required for break through attacks of highly

Fig. 3: Limbal VKC with Horner-Trantas dots (For color version see plate 20)

Fig. 4: Shield ulcer (For color version see plate 20)

active VKC. The pulse therapy strategy²³ involves instillation of one percent prednisolone acetate or phosphate four times daily for two days, with subsequent tapering to three times daily for succeeding two days, twice daily for two days after that, once daily for an added three days and subsequent discontinuation thereafter. For extreme mucus production 10 to 20 percent N-acetylcysteine drops four times daily used and for persistent epithelial defect bandage soft contact lens may be used.

Atopic Keratoconjunctivitis

Atopic keratoconjunctivitis is a severe chronic inflammatory disorder involving eyelid skin, cornea, conjunctiva and lens that is commonly seen in association with atopic dermatitis.¹¹ It usually appears in late teens and progress into fifth decade of life.

Symptoms

It includes bilateral ocular itch, burning and foreign body sensation, excessive tearing and profuse mucoid discharge, lid eczema.²³ Symptoms are more severe in winter. Family history of atopy is present. Clinical signs are conjunctival hyperemia, episcleral vessels, papillae on upper tarsal conjunctiva and presence of chronic blepharitis. In severe cases conjunctival scarring, fornix shortening, symblepharon, corneal ulceration and neovascularization, cataract formation may occur.²⁶

Treatment

It includes antihistaminic and mast cell stabilizing drops, topical steroids. In case of acute exacerbations frequent topical corticosteroids should be initiated with topical mast cell stabilizers. The corticosteroids are then tapered off over two to three weeks. Topical cyclosporine (0.5% to 2%) can be used if symptoms persist after removal of steroid.

Giant Papillary Conjunctivitis

Giant papillary conjunctivitis is an immune response to long-term exposure to foreign bodies in the eye like

deposits on ocular prostheses,²⁷ exposed sutures,²⁸ contact lenses.²⁹ It develops as a result of tarsal conjunctival sensitization to allergic material present on surface of contact lens together with trauma to the upper tarsal conjunctiva due to excursion of eye lid over contact lens at each blink.²³

Symptoms

Common symptoms are itching, mucus production, decreasing contact lens tolerance. Examination of upper tarsal conjunctiva reveals conjunctival hyperemia and giant papillae greater than 1 mm in diameter.²³ The cobblestoning is more easily seen with cobalt blue light source after instilling fluorescein dye.

Treatment

Treatment involves reducing contact with source of irritation. In patients who want to continue contact lens wear- proper lens hygiene, modification of contact lens material (low cost disposable lens), limitation of contact lens wearing time are to be advised. A mast cell stabilizer along with low potency topical steroid for short period can help in resolution of conjunctival changes.⁶

Contact Dermatitis

Contact dermatitis is an inflammation of the eyelid skin or conjunctiva or both resulting from exposure to allergens or irritants.³⁰ Allergic contact dermatitis is due to a type IV hypersensitivity reaction whereas the irritant contact dermatitis is due to direct toxic effect of the irritant.

It is usually caused by topical drugs or cosmetics. Topical drugs implicated in contact dermatitis are:³⁰⁻³²

- Preservatives—Benzalkonium chloride, Thiomersal
- Antiglaucoma drugs:
 - Prostaglandin analogs—Latanoprost
 - Beta blockers—Timolol
 - Carbonic anhydrase inhibitors—Dorzolamide, Brinzolamide
 - Parasympathomimetics—Pilocarpine
 - Sympathomimetics—Brimonidine

Points	Bacterial conjunctivitis	Viral conjunctivitis	Allergic conjunctivitis
Common etiologic agent	<i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> <i>Neisseria gonorrhea</i> <i>Chlamydia trachomatis</i>	Adenovirus Herpes simplex virus Herpes zoster virus Enterovirus	Pollens Animal danders Allergen
Prevalent age	Neonate to toddlers	School age to adults	Late childhood to early adulthood
Type of discharge	Purulent	Watery	Mucoid
Smear of exudates	Neutrophils, Bacteria	Lymphocytes	Eosinophils
Lymphadenopathy	Occasional	Common	None
Slit lamp findings	Papillary response	Follicular response	Chemosis, mild congestion
Associated symptoms	Otitis media	Pharyngitis	Rhinitis, asthma, eczema
Treatment	Antibiotics	Cold compress Artificial tears Topical vasoconstrictors Antivirals	Antihistaminics Mast cell stabilizers Decongestants NSAIDs

- Anti inflammatory drugs—Ketorolac, Corticosteroids
- Antimicrobials—Aminoglycosides, Sulfonamides, Cefazolin, Vancomycin, Chloramphenicol
- Antivirals—Acyclovir
- Antiallergic drugs—Chlorpheniramine maleate, Sodium cromoglycate
- Anesthetics—Proparacaine
- Mydriatics and cyclopegics

Clinical Features

Features of contact dermatitis are pruritus, erythema, edema, vesiculation in acute dermatitis and may be associated with scaling and desquamation in chronic cases.

Treatment

Avoidance of the causative agent and topical corticosteroids for about 5 to 10 days.

Subconjunctival Hemorrhage

Subconjunctival hemorrhage is diagnosed clinically. Patient usually presents with a bright red eye preceded by a trauma. Vessel details are not visible.

Treatment: Patient is reassured that it is a harmless condition with blood reabsorption occurring over a few weeks and no treatment is needed. Ocular lubricants may be given.

DISORDERS OF SCLERA

Scleritis is uncommon in children but can occur in association with juvenile rheumatoid arthritis or infections with herpes simplex virus, tuberculosis, mumps, syphilis and varicella. Episcleritis occurs in association with systemic diseases like erythema multiforme, syphilis and severe drug allergies (e.g. penicillin).¹⁰

Clinical features: It usually presents with localized area of redness (Fig. 5). Pain is usually associated with scleritis

and not with episcleritis. Topical phenylephrine constricts the vessels of the conjunctiva but not of the episclera or sclera and thus helps in differentiating conjunctivitis from scleritis or episcleritis.

Treatment: It involves managing the underlying condition. Supportive care includes use of artificial tears, non-steroidal anti-inflammatory agents. Topical steroids may be useful for severe cases.

CHILDHOOD GLAUCOMA

Childhood glaucoma can be simply classified as primary or secondary. Primary glaucomas, often genetic in origin comprise those in which a developmental abnormality of the anterior chamber angle leads to aqueous outflow obstruction. It can further be divided into primary congenital glaucoma, developmental glaucoma and juvenile open angle glaucoma. In developmental glaucoma associated ocular and systemic anomalies are typically present. In secondary childhood glaucomas, aqueous outflow obstruction is acquired from usually an inflammation or neoplasia.³³

Clinical Features

The classic triad of features of primary congenital glaucoma are epiphora (excessive tearing), photophobia, blepharospasm. The parents also complain of redness, large cornea. On examination there is increased corneal diameter, corneal edema, refractive error, raised intraocular pressure (IOP). Gonioscopy to view the angle structures can be done in an infant using koepple gonioslens along with a portable slit lamp for illumination and magnification. Fundoscopic evaluation of the optic nerve is essential. Cupping of optic nerve head proceeds more rapidly in infants and is more likely to be reversible if pressure is lowered early. In older children visual fields should be tested.

Treatment

An early reduction in IOP should be targeted to reduce corneal edema and chances of optic nerve damage. Definitive treatment of primary congenital glaucoma is surgical usually a combination of trabeculectomy with trabeculotomy is done. Medical therapy plays an adjunctive role. Preoperative medications may help to clear the cornea and facilitate angle surgery and postoperatively they may help control IOP until adequacy of surgical procedure has been established.

UVEITIS

Uveitis is defined as inflammation of any part of the uveal tract (iris, ciliary body, choroid). Children accounts for only 2.2 to 13.8 percent of patients in many uveitis clinics.³⁴ But it is significant for causing numerous complications, many of which are vision threatening.³⁵ These complications increase with duration of disease. So an early diagnosis and prompt referral to an ophthalmologist is essential in these cases. Anterior uveitis is most common

Fig. 5: Localized congestion in scleritis
(For color version see plate 20)

Fig. 6: Anterior uveitis with posterior synechiae
(For color version see plate 20)

followed by intermediate uveitis, posterior uveitis, and panuveitis. The most common cause of anterior uveitis is juvenile idiopathic arthritis whereas for intermediate uveitis it is idiopathic. The most frequent type of posterior uveitis is toxoplasmic retinochoroiditis.³⁶

Clinical Features

Presenting features are red eye, pain, reduced vision, floaters and photophobia. On examination on the slit lamp biomicroscope anterior chamber cells and flare (Fig. 6), retrolental cells are usually seen. Indirect ophthalmoscopy reveals vitreous exudates in intermediate uveitis and toxoplasma scar in posterior uveitis.

Complications

The most common causes of vision loss in children with uveitis are cataract, band keratopathy, glaucoma, cystoid macular edema.³⁶

Treatment

Treatment needs to be individualized depending on the suspected etiology of the disease. The medications include cycloplegics, corticosteroids (topical, local injection, intravenous, oral or combination) non steroidal anti inflammatory drugs or drugs like sulfasalazine, methotrexate, azathioprine, mycophenolate mofetil, leflunomide, cyclosporine, tacrolimus, etanercept, infliximab, intravenous immunoglobulin, alpha interferon, adalimumab and daclizumab.

DISORDERS OF THE EYELIDS

Blepharitis

Blepharitis is an inflammation of the eyelid that is often associated with conjunctivitis and keratitis. It can be

Fig. 7: Blepharitis with crusting around base of cilia
(For color version see plate 21)

anatomically subdivided into anterior and posterior. Anterior blepharitis is the inflammation of the eyelids and follicles while posterior blepharitis involves meibomian glands. Anterior blepharitis is usually infectious- bacterial (*Staphylococcus*), viral (Molluscum contagiosum) and parasitic (Phthiriasis) or seborrheic.³⁷ Posterior blepharitis may be either be seborrheic, obstructive or a combination of both or may be associated with acne rosacea which is rare in children.

Clinical Features

Common symptoms of blepharitis are irritation, burning sensation, tearing, photophobia, blurred vision, red eyes. These are usually worse in the morning because during sleep inflamed lids are in close contact with ocular surface and there is also a decrease in tear production which is associated with constant release of inflammatory mediators.³⁷

Examination reveals telangiectatic vessels of eyelid margin, inspissated meibomian gland, conjunctival hyperemia, punctate keratopathy, corneal ulceration. Hard crusts around base of cilia are typically found in staphylococcal blepharitis (Fig. 7). Seborrheic blepharitis is characterized by soft crusts, lipid secretion and hyperemia at the lid margin. Long standing chronic blepharitis presents with hypertrophy of lid margins, scars, trichiasis, madarosis, poliosis, chalazion ulceration of lid margins. In posterior blepharitis symptoms are more pronounced than signs. Pressure on tarsus releases a thick lipid secretion.

Treatment

The mainstay of treatment is maintaining eyelid hygiene for a prolonged period. Warm compresses followed by light scrubbing of the eyelid with a cotton swab dipped in a mixture of baby shampoo and water is to be done. For patients with staphylococcal blepharitis a topical antibiotic is to be applied. In severe cases oral antibiotics may be prescribed. Erythromycin is usually used for young

Fig. 8: Stye (For color version see plate 21)

children and doxycycline for older children. Topical corticosteroids may be helpful in patients with marked inflammation.³⁸ As many patients with blepharitis have aqueous tear deficiency artificial tears may improve the symptoms. Any associated skin condition should be treated.

HORDEOLUM

It is an acute focal inflammation of the eyelid with abscess formation. It can be of two types:

- *Internal Hordeolum:* Infection of the meibomian gland.
- *External Hordeolum (stye):* Infection of the gland of zeiss (Fig. 8).

Most common bacteria causing hordeolum is *Staphylococcus aureus*.³⁹

Symptoms: Presenting symptoms are pain, redness, swelling of eyelids.

Treatment: It is usually self limited and resolves within five to seven days with spontaneous drainage of abscess. Conservative management includes warm compress and topical antibiotics. Systemic antibiotics can be used if there is associated cellulitis.

Chalazion

Chalazion is a chronic lipogranulomatous inflammation of the meibomian glands (internal hordeolum) due to obstruction of the gland orifices on the eyelid margin. Sebum of the gland is released into the tarsus and surrounding soft tissues resulting in an inflammatory response. *Staphylococcus aureus* has been implicated in these lesions. Seborrhea, acne, blepharitis all predispose to chalazion.

Clinical Features

It presents as a painless slowly enlarging lump in either lid, usually away from the lid margin. A large centrally located chalazion may result in visual disturbances

and astigmatism. It can rarely lead to conjunctivitis or cellulitis.

Treatment

Conservative treatment is the first line of management. Warm compress for three to five minutes two to four times daily should be given. This should be followed by massage of the eyelids to release the chalazion contents. Topical antibiotics may be used. Intralesional injection of steroid (triamcinolone acetonide) helps in healing but carries risk of hypopigmentation of overlying skin.⁴⁰⁻⁴²

Large persistent chalazion requires surgical drainage and curettage. A study conducted by Mustafa et al⁴³ in children found that the three procedures of intralesional corticosteroid injection, incision and curettage and a combination of these two techniques were safe, effective and convenient. He also found that intralesional corticosteroid injection is good for patients with allergy to local anesthesia and chalazion close to the lacrimal drainage system. He recommended incision and curettage for patients with infected chalazia and the combined treatment for large, recurrent and multiple chalazia.

PRESEPTAL AND ORBITAL CELLULITIS

The orbital septum is a membranous sheet that extends from the orbital rim to the eyelids and acts as the anterior boundary of orbit. Infection and inflammation of tissues anterior to orbital septum constitutes preseptal cellulitis, whereas extension into the postseptal orbital tissues constitutes orbital cellulitis. In children *Staphylococcus aureus* or nonhemolytic streptococci, Group A beta hemolytic streptococci, *Staphylococcus aureus* and *Haemophilus influenzae* are the most commonly associated.⁴⁴

Spread

Infection reaches orbit by three methods—Implantation, local extension or hematogenous spread. Ethmoidal sinusitis is the most common predisposing cause for orbital cellulitis.⁴⁵

Clinical Features

It is twice more common in males than females. Preseptal cellulitis tends to occur in children younger than five years whereas postseptal involvement occurs predominantly in children older than five years child usually presents with pain, redness, swelling of periorbital region. There may be associated fever, malaise. A thorough history of upper respiratory tract infection, lacrimal outflow obstruction, sinusitis and trauma has to be taken. On examination presence of proptosis, restriction of extraocular movements or loss of vision along with periorbital edema, are features of postseptal spread of infection.²³ Signs of meningitis must also be sought for.

Diagnosis

A complete blood count should be obtained as white cell count is often elevated. Pus and blood cultures should be sent. Computed tomography with contrast is needed for identifying sinusitis, presence of subperiosteal or orbital abscess. Magnetic resonance imaging is especially useful for diagnosis of cavernous sinus thrombosis and intracranial extension. Ultrasound is of limited use.

Treatment

Mild preseptal disease with no constitutional symptoms and willing for frequent follow-ups are managed with oral antibiotics from the outpatient department. However, if child looks toxic, diagnosis is unclear or orbital cellulitis or abscess is suspected then patient is hospitalized, imaging ordered and parenteral antibiotics initiated. Currently the initial choice for parenteral therapy is ampicillin-sulbactam. Vancomycin or clindamycin can be added in sick children in view of increasing methicillin resistant *Staphylococcus aureus*. Indications for surgical intervention that is drainage of abscess are large abscess, ophthalmoplegia, decreasing vision, lack of improvement despite 48 hours of aggressive medical management.

CONCLUSION

Children presenting with red eyes to the pediatrician are very common. It is essential that a thorough history is taken and a systematic physical examination is performed. Once a diagnosis is made and a vision threatening etiology is ruled out, immediate treatment followed by a close follow-up ensures good prognosis. Although most cases can be followed up by the primary care physician, prompt referral to a trained ophthalmologist must be considered in cases with danger signs to prevent severe complications.

Binocular Vision, Ocular Motility, Squint and Amblyopia

AK Grover, Shaloo Bageja

ANATOMY AND PHYSIOLOGY OF THE OCULAR MOTILITY

Three factors are important for coordination between the two eyes. These are the six extraocular muscles, three cranial nerves and the higher brain functions.

- *Extraocular muscles:* There are six extraocular muscles controlling eye movement: the four rectus muscles (medial, lateral, superior, inferior), and two oblique muscles (superior and inferior) (Fig. 1)

While the medial and lateral rectus muscles are responsible for (in turning) and abduction (out turning) of the eye. The superior and inferior rectus, and the superior and inferior oblique muscles each have primary and secondary actions, depending of the position of the eye (Table 1).

Unocular movements are called 'ductions' and binocular movements are called 'versions'. When the eyes are looking straight ahead, they are said to be in the primary position. There are six cardinal position of gaze

Table 1: Showing actions of extraocular muscles

Muscle	Primary action	Secondary action	Tertiary action
Medial rectus	Adduction		
Lateral rectus	Abduction		
Superior rectus	Elevation	In torsion	Adduction
Inferior rectus	Depression	Ex torsion	Adduction
Superior oblique	In torsion	Depression	Abduction
Inferior oblique	Ex torsion	Elevation	Abduction

(i.e. directed to one side or the other; either looking out and up, straight out or out and down) or into one of the two midline vertical positions (looking directly up or directly down) (Fig. 2). Deviations from these positions of gaze provide the basis for diagnosis of a squint.

- *Cranial nerves:* The extraocular muscles are supplied by the third, fourth and sixth cranial nerves. All the ocular

Fig. 1: Extraocular muscles (Courtesy: Khurana AK. Strabismus and Nystagmus. In: Comprehensive Ophthalmology, 4th edn 2007.pp. 313-37)

Fig. 2: Action of extraocular muscles. SR- superior rectus, MR- medial rectus, IR- inferior rectus, SO- superior oblique, LR- lateral rectus, IO-inferior oblique (Courtesy: Khurana AK. Strabismus and Nystagmus. In Comprehensive Ophthalmology, 4th edn. 2007.pp. 313-37)

movements occur due to third cranial nerve other than lateral abduction (lateral rectus) which is generated by the sixth (abducent) cranial nerve and a downward, inward gaze (such as looking where to put your feet when going down a flight of steps—superior oblique) which is generated by the fourth (trochlear) cranial nerve.

- *The higher brain centers:* The third, fourth and sixth brainstem nuclei ensure the correct functioning of their relevant cranial nerves. There exists a highly accurate supranuclear control of eye movements which keeps the two eyes yoked together so that the image of the object of interest is simultaneously held on both foveas despite movement of the perceived object or the observer's head and/or body. The higher cortical centers control the speed of eye movements either when following a moving target (pursuit) or jumping from one target to another (saccades).

BINOCULAR SINGLE VISION

When a normal individual fixes his visual attention on an object of regard, the image is formed on the fovea of both the eyes separately; but the individual perceives it as a single image. This state is called binocular single vision. It is a conditioned reflex and is not present at birth (Table 2).¹

ANOMALIES OF BINOCULAR VISION

Anomalies of binocular vision include:

- *Suppression:* It is a temporary active cortical inhibition of the image of an object formed on the retina of the squinting eye when both eyes are open.
- *Amblyopia:* Amblyopia is derived from two Greek words (amblys-dull, ops-eye), literally meaning dull vision. It is a partial loss of vision in one or both eyes, in the absence of any organic disease of ocular media, retina and visual pathway. The most sensitive period for development of amblyopia is first six months of life and it usually does not develop after the age of 6 years.

It can be broadly classified as functional (reversible) or organic (irreversible). The other classification based on the etiology includes five major types:

- Amblyopia ex anopsia (stimulus deprivation, e.g. due to a cataract or corneal opacity)
- Congenital amblyopia (organic)
- Anisometropic amblyopia (associated with difference in refractive error between two eyes)
- Ametropic amblyopia (associated with uncorrected refractive error, correctable by using glasses)
- Strabismic amblyopia (associated with squint).

- *Abnormal retinal correspondence (ARC):* In a state of normal binocular single vision, there exists a precise physiological relationship between the corresponding points of the two retinae. Thus, the foveae of two eyes act as corresponding points and have the same visual direction. This adjustment is called normal retinal correspondence (NRC). When squint develops, patient may experience either diplopia or confusion. To avoid these, sometimes (especially in children with small degree of esotropia), there occurs an active cortical adjustment in the directional values of the two retinae. In this state fovea of the normal eye and an extrafoveal point on the retina of the squinting eye acquire a common visual direction (become corresponding points). This condition is called abnormal retinal correspondence (ARC) and the child gets a crude type of binocular single vision

- *Confusion and diplopia:* Binocular diplopia is due to formation of image on dissimilar points of the two retinae. This is due to paralysis of extraocular muscle or post-traumatic orbital floor fracture due to entrapment of the muscle.

SQUINT

Squint refers to a misalignment of the eyes. The image is therefore, not in corresponding areas of both eyes, which may result in eventual amblyopia in childhood or diplopia in adulthood.

CLASSIFICATION OF STRABISMUS

There are a number of ways of classifying squints. It can be congenital (onset before six months of age) or acquired. It can be intermittent or constant.

Broadly, strabismus can be classified as below:

- Apparent squint or pseudostrabismus.
- Latent squint (Heterophoria)
- Manifest squint (Heterotropia)
 - Concomitant squint
 - Incomitant squint.

Pseudostrabismus

It is a condition in which in spite of parallel visual axis, the eye seems to be squinting. This may occur in children before adequate depth of medial canthus develops.

Table 2: Showing important milestones in visual development

Age	Milestones
At birth	No central fixation, eyes move randomly
By first month of life	Fixation reflex starts developing, establishes by sixth month
By six month	Macular stereopsis and accommodation reflex develops
By 6 years	Full visual acuity (6/6) is attained and binocular single vision is developed

Pseudoesotropia (i.e. eye appears to turn inward) is usually seen in a patient with prominent epicanthal fold and Pseudoexotropia (i.e. eye appears to turn outward) in hyper-teleroism.

Latent Squint (Heterophoria)

It is a condition in which the eye tends to deviate whenever the fusion breaks. Therefore, when the influence of fusion is removed the visual axis of one eye deviates away. It is called orthophoria when the two eyes are perfectly aligned. The tendency to converge is esophoria. The tendency to diverge is exophoria.

Finally, the prefixes 'hypo' and 'hyper' refer to a downward or upward deviation respectively. This form of squint is less common.²

Concomitant Squint

It is a type of manifest squint in which the amount of deviation in the squinting eye remains constant in all the directions of gaze and there is no associated limitation of ocular movements. It can be due to sensory and motor obstacles such as refractive errors, anisometropia, corneal opacities, cataract, diseases of macula (e.g., central chorioretinitis), optic atrophy, ptosis, congenital abnormalities of orbit and extraocular muscles.

Epidemiology

- *Ocular misalignments are common in newborns*: one study found the prevalence of these to be about 73 percent in one month-old babies, reducing to 50 percent in two month-old babies and virtually disappearing in normal four month-olds.³
- Pathological misalignment is prevalent among older children, affecting about 5 percent of 5 year-olds⁴ (of these, 60 percent have eso-deviations and 20 percent have exo-deviations). This drops to ~3 percent in the 13 to 24 years old age group.

TYPES OF CONCOMITANT SQUINT

Three common types of concomitant squint are:

- Convergent squint (esotropia)
- Divergent squint (exotropia)
- Vertical squint (hypertropia).

Convergent Squint (Esotropia)

It is the inward deviation of one eye. It can be unilateral (i.e. one eye only deviates always while the second normal eye takes fixation) or alternating (either of the eyes deviates inwards when the other eye takes up fixation).

It can be:

- Accommodative esotropia
- Nonaccommodative esotropia
- Secondary esotropia.

- *Accommodative esotropia*: It occurs due to overaction of convergence associated with accommodation reflex. It is of three types: refractive, nonrefractive and mixed (Figs 3A and 3B).

- *Nonaccommodative esotropias*: It includes all those primary esodeviations in which amount of deviation is not affected by the state of accommodation.

It includes:

- Essential infantile esotropia. It may present anytime after birth or within the first 6 months of life. It is characterized by fairly large angle of squint ($>30^\circ$), alternate fixation in primary gaze and crossed fixation in lateral gaze.
- Essential acquired or late onset esotropia. It typically occurs during first few years of life.

- *Secondary esotropia*

It includes:

- Sensory deprivation esotropia. It results from monocular lesions (in childhood) which either prevent the development of normal binocular vision or interfere with its maintenance such as cataract, severe congenital ptosis, aphakia, anisometropia, optic atrophy, central chorioretinitis, etc.
- *Consecutive esotropia*: It is due to overcorrection following surgery for exotropia.

Divergent Squint (Exotropia)

It is the outward deviation of the eye. It can be unilateral or alternating.

It has been classified into following types:

- *Congenital exotropia*: It is quite rare and is usually present at birth.

Figs 3A and B: Fully accommodative squint (Courtesy: vision-centreindore.com/eyedisease_children.html) (For color version see plate 21)

- *Primary exotropia:* It usually starts as intermittent squint in early childhood and is associated with normal fusion and no amblyopia. Precipitating factors include bright light, fatigue, ill health and day-dreaming. If not treated in time it decompensates to become constant exotropia. Steropsis is usually absent
- *Sensory exotropia:* It is a constant unilateral deviation which results from long standing lesions (in adults) (Fig. 4), associated with poor vision in the affected eye e.g. traumatic cataract, corneal opacity, optic atrophy, retinal detachment and macular lesions
- *Consecutive exotropia:* It is a constant unilateral exotropia which results due to surgical overcorrection of esotropia.

EXAMINATION

History

A meticulous history is very important. It should include: age of onset, duration, mode of onset (sudden or gradual), any illness preceding squint (fever, trauma, infections, etc.), intermittent or constant, unilateral or alternating, history of diplopia, family history of squint, any history of use of glasses or previous surgery and so on.

Inspection

- Type of squint—convergent or divergent squint.
- A young baby should be examined for the presence of epicanthal folds (crescentic folds of skin on each side of the nose) which could give rise to pseudoesotropia: the impression that the eyes are turned inwards when in fact they are not.
- Look for facial asymmetry (either craniofacial abnormalities or head tilt) and obvious eye abnormalities, e.g. ptosis or proptosis.

Fig. 4: Twenty-four-year-old male showing divergent squint in the left eye (For color version see plate 21)

Hirschberg's Test

This gives a rough estimate of the degree of strabismus. Hold a pen torch about an arm's length (~33 cm) away from the patient and shine it in front of their eyes. Ask the patient to look at the light, if possible. Observe where the reflection of the pen torch lies with respect to the cornea. It should be central bilaterally. If it lies at the inner margin of the pupil, there is an outward deviation (exotropia) of the eye. If it lies at the outer margin, an esotropia is present. Roughly, the angle of squint is 15° and 45° when the corneal light reflex falls on the border of pupil and limbus, respectively (Fig. 5).

Cover/Uncover Test

An object to focus on is held in front of the patient who is instructed to focus on it. One eye is completely occluded for few seconds and the uncovered eye is observed for movement as it focuses on the object. This eye is then covered and the other eye is observed for movement. Movement of the eye outwards confirms that there is an esotropia (i.e. the eye was turned inwards initially) and vice versa for exotropia. The test is repeated for objects at 6 meters and far distance.

Alternate Cover Test

This is done in a similar fashion to the previous test but the occluder is rapidly switched from one eye to the other. There is now no longer bifoveal stimulation (so each eye is seeing a separate image). Observing the eye movement as the occluder is removed, note whether it moves inwards (i.e. there is a latent exophoria and the eye has to move in to see again) or outwards (revealing a latent esophoria).

Ocular Movements

Both uniocular as well as binocular movements should be tested in all the cardinal positions of gaze.

Fig. 5: Hirschberg corneal reflex test. Courtesy: (Khurana AK. Strabismus and Nystagmus. In: Comprehensive Ophthalmology, 4th edn.2007.pp.313-37)

Pupillary Reactions

These may be abnormal in patients with secondary deviations due to diseases of retina and optic nerve.

Media and Fundus Examination

It may reveal associated disease of ocular media, retina or optic nerve.

Visual Acuity Assessment and Refraction

It is most important, because a refractive error may be responsible for the symptoms of the patient or for the deviation itself. Preferably, refraction should be performed under full cycloplegia, especially in children.

MEASUREMENT OF ANGLE OF DEVIATION

It is performed by:

- Prism bar cover test
- Krinsky corneal reflex test
- Synoptophore.

Tests for grade of binocular vision and sensory functions

- Worth's four-dot test
- After image test
- Test for fixation
- Sensory function test with synoptophore
- Neutral density filter test.

MANAGEMENT

- Needs referral
 - A neonate with a constant squint or with a squint that is worsening from two months of age should be referred to an ophthalmologist.³
 - Any older child with a suspected squint should be seen in the eye clinic.
 - Any acute onset squint should be referred.
 - The earlier the referral, the better chance the child has of avoiding the possibility of amblyopia.
- Treatment is guided by the exact nature of the squint and by the patient's age
- *Refractive error correction:* Correction of refractive errors will be the important first step in the management of these individuals
- *Amblyopia management:* If amblyopia is present, will need management before any surgical intervention.⁵ A number of forms of treatment have been devised, however, whatever the method employed the need for early diagnosis and treatment cannot be overstressed. Correction of the basic pathology either a refractive error, or a cataract or strabismus is the first step in management. The main stay of treatment includes occlusion therapy which involves covering the better eye so as to stimulate development of vision in the amblyopic eye. If the treatment is begun early

and carried out meticulously it gives very satisfactory results. A definitive protocol for occlusion has to be chalked out for all the individual cases depending on the age and density of amblyopia. The other forms of treatments include the red filter treatment and drug penalisation. Drug penalisation involves use of medicines to paralyse ciliary body of the better eye so that the weaker eye may be used to overcome amblyopia. Pleo-optics, visual exercises and Cambridge vision stimulator (CAM) are the other systems available which have been used in the past but are largely out of use today

- *Surgery:* Patients may go on to have surgical alignment after refractive correction and amblyopia therapy if required. A combination of muscle recession (it is moved backwards on the globe and so its action is weakened) and antagonistic muscle resection (a segment of muscle is removed, so strengthening its action) is used with the aim to restore binocular function. Sometimes, adjustable sutures are used to enable minor corrections to be made without having to go through a further full surgical procedure.⁶

INCOMITANT SQUINT

- Paralytic squint
- A-V pattern heterophorias
- Restrictive squint.

Paralytic Squint

This refers to the deviation of eye due to paralysis of one or more extraocular muscles. It can be due to neurogenic (encephalitis, meningitis or brain tumors involving nuclei or nerve, diabetes, hypertension) or myogenic lesions (myositis, trauma, thyroid myopathy) or due to lesions at the level of neuromuscular junction (myasthenia gravis).⁷

Clinical Features

- Confusion and diplopia
- Restriction of eye movement
- Compensatory head posture
- False projection
- Past pointing.

Pathological Sequel of an Extraocular Muscle Palsy

In all cases of extraocular muscle palsy, certain sequel take place after some time. These occur more in paralysis due to lesions of the nerves than the lesions of muscles. These include:

- Overaction of the contralateral synergistic muscle.
- Contracture of the direct antagonist muscle.
- Secondary inhibitional palsy of the contralateral antagonist muscle.

Isolated Nerve Palsies

Third cranial nerve:

- *Presentation:* There may be external ophthalmoplegia where there are partial or complete motility problems resulting in varying degrees of squint.
 - Eyeball is turned down, out and slightly intorted due to action of lateral rectus and superior oblique.
 - There may be internal ophthalmoplegia (partial or complete impairment of pupillary reactions).
 - There may also be a ptosis.
- *Etiology:* Pupil-sparing causes tend to relate to ischemic microvascular disease (and rarely, cavernous sinus syndrome). Pupil-involving disease usually arises as a result of an aneurysm but can also occur as a result of a tumor, trauma, pituitary apoplexy, herpes zoster and leukemia. Children may exhibit this as part of an ophthalmoplegic migraine.

Fourth Cranial Nerve

- *Presentation:* Binocular vertical diplopia, difficulty in reading and the head tilt.
- *Etiology:* This may also be congenital or idiopathic. It may be due to trauma, vasculopathy (often related to diabetes and hypertension) and demyelinating disease.

Sixth Cranial Nerve

- *Presentation:* Horizontal diplopia which is most pronounced on lateral gaze on the affected side.
- *Etiology:* Vasculopathy (usually diabetic, hypertensive or atherosclerotic) and trauma are the most common causes but it is also often idiopathic. Less common causes include an increase in intracranial pressure, cavernous sinus mass, multiple sclerosis, giant cell arthritis, inflammation and infection. Children may also get this as a benign, postviral (or postvaccination) condition as well as due to increased intracranial pressure and Gradenigo's syndrome (multiple cranial nerve palsies associated with complicated otitis media).

Double Elevator Palsy

Presentation: It is characterized by paresis of the superior rectus and the inferior oblique muscle of the involved eye.

Etiology: It is a congenital condition caused by third nerve nuclear lesion.

Multiple Nerve Palsies

- *Presentation:* there may be a combination of unilateral III, IV and VI cranial nerves resulting in limitation of eye movement (and therefore diplopia), facial pain corresponding to one or more branches of the V cranial nerve, a ptosis and small pupil (Horner's syndrome) or a dilated pupil if the III cranial nerve is affected.

- *Etiology:* there are a number of conditions and syndromes which can give rise to this clinical picture:
 - Arteriovenous fistula (carotid-cavernous or dural-cavernous).
 - Tumors within the cavernous sinus (primary or metastatic).
 - Intracavernous aneurysm.
 - Mucormycosis (particularly in uncontrolled diabetic and immunocompromised patients).
 - Pituitary apoplexy.
 - Herpes zoster.
 - Cavernous sinus thrombosis.
 - Tolosa-Hunt syndrome.
 - Rarely sarcoidosis, Wegener's granulomatosis, tuberculosis.

Investigations of a Case of Paralytic Squint

In addition to basic squint examination, a paralytic squint requires additional tests:

- Diplopia charting
- Hess screen test
- Forced duction test.

Management

- *Treatment of the cause:* If squint is due to any cause, it should be managed accordingly.
- *Conservative measures:* One should wait and watch for self-improvement to occur for a period of 6 months. One can prescribe vitamin B-complex as neurotonic and systemic steroids for nonspecific inflammations.
- *Treatment of annoying diplopia:* It includes use of occluder on the affected eye to prevent confusion and diplopia.
- *Surgical treatment:* It should be carried out in case the recovery does not occur in 6 to 12 months.
- *Aim of treatment:* Is to provide a comfortable field of binocular fixation, i.e. in primary gaze and lower quadrants.
- *The principles of surgical treatment:* Involve strengthening of the paralysed muscle by resection; and weakening of the overacting muscle by recession.

'A' and 'V' Pattern Heterotropia

When the amount of deviation varies more than 10° and 15° upward and downward gaze, they are called 'A' or 'V' pattern squint respectively.

A' and 'V' esotropia: In 'A' esotropia the amount of deviation increases in upward gaze and decreases in downward gaze. The reverse occurs in 'V' esotropia.

Restrictive Squint

In restrictive squint, restriction of the extraocular muscle is not due to nerve palsy but it is mechanically restricted. Forced duction test is positive (i.e. a restriction is encountered on passive rotation).

Common causes of restrictive squint are:

- Duane's retraction syndrome
- Brown's superior oblique tendon sheath syndrome,
- Strabismus fixus
- Dysthyroid ophthalmopathy
- Incarceration of extraocular muscle in blow-out fracture of the orbit.

DUANE'S SYNDROME

In this condition, there is unilateral or bilateral lateral rectus activity during adduction and reduced activity in abduction. This results in a limited ability to abduct the eye and a narrowing of the palpebral aperture on adduction (as, effectively, both medial and lateral recti are acting simultaneously). Most cases are managed conservatively, as there is no amblyopia due to the eyes being straight in the primary position. If this is not the case, surgery will be performed to correct it.

BROWN'S SYNDROME

This condition may be congenital or acquired (iatrogenic or inflammatory—Rheumatoid arthritis, pansinusitis or scleritis) and is characterised by malfunction of the trochlear nerve or the superior oblique. Congenital cases are occasionally treated with surgery and acquired cases may respond to a course of steroids along with treatment of the underlying cause.

DYSTHYROID EYE DISEASE

Graves' disease is due to an autoimmune disorder. Ocular changes includes painful red eye, a reduced visual acuity,

proptosis, lid retraction and lid lag. These patients may also have restricted eye movements (particularly elevation and abduction) giving rise to a squint with diplopia.

STRABISMUS FIXUS

It is a rare condition characterized by bilateral fixation of eyes in convergent position due to fibrous tightening of the medial recti.

ORBITAL BLOW OUT FRACTURES

These are isolated comminuted fractures which occur when the orbital walls are pressed indirectly, 'Blowout fractures' mainly involve orbital floor and medial wall. Orbital soft tissue with extraocular muscle may incarcerate in the fracture resulting in restriction of the ocular motility.

Visual Assessment and Screening in Children

Digvijay Singh, Amit Khosla, Rohit Saxena

INTRODUCTION

An accurate visual assessment is critical to diagnosis and follow-up of most pediatric ophthalmic disorders. The term visual assessment encompasses a large number of visual function parameters prominent among which are visual acuity, color vision, contrast sensitivity, visual fields, binocularity/stereopsis and vision related electrophysiology. Perhaps the single most important of this list would be visual acuity since that is representative of the extent of the disease and the consequent disability it generates. In this chapter, we discuss the various methods that may be used for visual assessment in various age groups and interpretation of the results. We also discuss the need and protocol of screening for common ophthalmic disease in children.

VISUAL DEVELOPMENT

The pediatrician must be aware of the normal milestones that mark the development of the visual system to correctly ascertain whether a particular finding is abnormal. Any delay in these milestones is a red herring and should pave way for further examination and investigations of the ocular and nervous system. Table 1 defines broadly, the most common milestones of the developing visual system and the expected visual acuity at various ages. These milestones have been used in various clinical and special tests for visual assessment.

VISION ASSESSMENT

Visual Acuity

“Visual acuity” refers to the ability of the eye to resolve an image and depends upon the optimal functioning of the retina and visual pathway. While this is easy to document in adults, visual acuity assessment in children is a different ball game altogether. Commonly, visual acuity is

represented in the form of a fraction where the numerator refers to the distance at which it is tested and denominator represents the actual line read by the patient. The normal visual acuity is 20/20 on the Snellen chart.

Clinical Assessment of Visual Acuity

While an accurate assessment of visual acuity may not be possible without the use of any special charts or equipment, a reasonable estimate may be made at the bedside by careful history taking and observation of the child.¹⁻³ During the period of observation, the child should be in the mothers lap or a comfortable position, cooperative and interested in the examiner.

Historical Clues

A well elicited history can give important clues to the visual status of the child. Some of the important questions to be asked are:

- Do the parents think that the child sees well
- Does the child hold objects close to his/her face to see them
- Do the eyes appear straight or deviated and are there any abnormal movements of the eyes
- Does the child close one eye or is there any drooping of the eyelids
- Was there any injury to the eyes, however minor it may be
- Is there any family history of ocular problems such as color blindness or glaucoma or early onset refractive errors, etc.
- Has there been any feedback from school regarding difficulty for the child in seeing the board or playing sports.

Observational Clues

For infants younger than six months, note the response the child has to a light source such as a torch. The child

Table 1: Development of vision and visual acuity

<i>Age</i>	<i>Visual Milestone</i>	<i>Visual acuity</i>
29 weeks gestation	Pupillary reactions to light	6/480-6/120 (by OKN)
30 weeks gestation	Dislikes and responds to bright light	
Birth	Blinks to light; prefers soft diffuse light	6/360 – 6/120 (by OKN)
1 week	Vetibulo-ocular reflex, Optokinetic nystagmus seen	
2 weeks	Small saccades develop; follows horizontal moving objects	
1 month	Fixation developing, can watch mothers face for prolonged time	6/480–6/120 (by PL tests)
2 months	Fixation well developed; bifoveal fixation; larger saccades; pursuits and convergence movements; follows vertically moving objects	6/120–6/60
3 months	Watches movements of own hands and reaches out towards interesting objects; prefers photographs to patterns	
4 months	Foveal differentiation complete; sensory fusion and accommodation begins to develops	6/120–6/30
5 months	Blink response to visible threat (menace response); grasps and explores objects; stereopsis begins to develop	6/90–6/24 6/12–6/6 (by VER)

18 months	Visual acuity at adult levels on pediatric acuity cards	6/18–6/7.5
3 years	Visual acuity at adult levels on snellen chart; contrast sensitivity well developed	6/15–6/7.5 (24 months) 6/12–6/6 (36 months)
5 years	Stereopsis fully developed	6/5
9 years	Critical period of monocular deprivation ends	

should show an interest in the light and attempt to follow it as the examiner moves it around. The examiner should then occlude one eye with his hand such that the hand is close to but not touching the eye. Now the response to a moving light source should be rechecked (for each eye separately). If the child resists occlusion of one eye, then it may mean a poorer visual acuity in the fellow eye. Also after the appropriate age, visual recognition of the mothers face can reliably point at some visual potential. Another bedside assessment that may be done is by using a direct ophthalmoscope to look at both the eyes from a distance of two to three feet. An asymmetrical red reflex may suggest a squint or a difference in refractive error between the two eyes. Also, examining the pupil responses can rule out any major visual deficit in the eyes.

For older infants, additionally, small objects such as candy pieces or brightly colored beads can be used to assess visual acuity. Also, children at this age group should be able to fix and maintain steady fixation for both stationary objects and moving objects in the near range of the child.

Toddlers and preschool children may be clinically assessed by whether the child can walk around without banging into obstacles and play with his/her peers and follow and catch objects such as a small ball or car, etc. Better

assessment may be made by their ability to recognize small shapes and objects and also by their ability to draw and color pictures. A rough estimate of visual acuity may be made by documenting the smallest object that the child can see and the approximate distance at which it was seen. The visual acuity (snellen equivalent in decimal units) in such a case is $0.3 \times \text{object distance (in mm)} / \text{object size (in mm)}$.

For school going children, their ability to read from books or appropriately draw and color detailed pictures as well as play sports is a sign of good visual functions. Formal visual acuity testing in such children is usually quite reliable and should always be attempted with the aid of special charts.

Formal Assessment of Visual Acuity²⁻³

Despite an excellent clinical bedside evaluation, the only way to accurately quantify visual acuity is by using equipment and charts designed for this purpose. These tests may determine either detection acuity (the smallest object that the eye can just detect) or resolution acuity (the minimum separation of pattern stimulus or highest frequency on a grating that the eye can resolve) or recognition acuity (the ability of the eye to detect and recognize objects or

letters). Of these the tests for recognition acuity are preferred to give a true picture of the visual ability of the eye though they may not be performed in very young children. While there have been numerous visual acuity tests developed and used over time, Table 2 mentions the most commonly used tests and the age group for which they are most appropriate.

Visual Evoked Response

This electrophysiological test records the change in the cortical electrical pattern detected by surface electrodes monitoring the occipital cortex following light stimulation of the retina. The stimuli could either be a flash of light or a checkerboard patterned. For purposes of visual acuity assessment, a pattern stimulus using varying sizes of the checkerboard squares reflecting 60, 30 and 15 seconds of arc is used. The smallest size to generate a reliable response is a good estimate of visual acuity. Along with Optokinetic nystagmus, this test tends to better estimate the true acuity than some of the other tests described below.

Optokinetic Nystagmus

Various tests directly or indirectly utilize the normal optokinetic nystagmus evoked by a revolving drum to estimate the visual acuity. In each of these, there is a varying size of grating or images on the drum and the smallest of which evokes an OKN response reflects the visual acuity. Prominent examples include the Catford drum which contains dots of varying size from 15 to 0.5 mm diameter and

oscillates at a distance of 60 cm from the child. These dots represent vision from 20/600 to 20/20. Similarly, there is the Harcourt's OKN drum which uses gratings of different resolution to detect acuity. This technique of testing tends to overestimate visual acuity.

Boeck Candy Bead Test

Multiple edible candy beads of variable sizes are shown to the child on the palm of the examiners hand. The smallest size that the child can see and reach out to eat is documented. This gives an approximate idea of the child's visual acuity.

Teller Acuity

This belongs to a group of tests based on the behavioral pattern of an infant to prefer to fixate a pattern stimulus rather than a blank, both being of the same brightness called as the preferential looking tests. Teller acuity cards are designed for a simpler and rapid testing particularly for children up to 18 months of age. These contain patches of square-wave gratings (vertical black and white stripes) which range in spatial frequency, from 38.0 cycles/cm to 0.32 cycles/cm changing in half octaves. This is equivalent to doubling of the denominator in snellen terms. When the child is unable to resolve a pattern, the whole pattern and card appears to be grey as the background of the card. A fixed testing distance of 38 cm for infants less than 6 months and 55 cm for children up to three years is used. The child is shown these patterned cards while a hidden

Table 2: Methods for visual acuity assessment in various age groups

<i>Age group</i>	<i>Methods used (Fig. 1)</i>	<i>Type of test/acuity</i>

observer is seeing the child's preference towards looking at these stimuli vis-à-vis a plain grey card. Till the child can see a pattern, he shows interest in seeing the card but when the size of the gratings gets too small to resolve, the child does not show any preference towards the card. This lack of fixation is noted by the observer and forms the basis of a reliable visual acuity. However, there are few drawbacks of this technique of testing which include the fact that it tests for near vision, and may miss small refractive errors. Also being resolution acuity, it may overestimate the vision and may miss out on amblyopia.

Cardiff Acuity

This test is based on vanishing optotype. The targets are pictures drawn with a white band bordered by two black bands, all on a neutral grey background. The average brightness of the picture is equal to that of the grey background. If the child's vision is good enough to resolve the white and black bands, the picture will be visible but if the bands are too narrow for the child to resolve them, the picture merges with the grey background, and simply becomes invisible. The visual acuity is reported on the basis of the smallest resolvable picture by the child.

Kay Picture Tests/Allen Test/LEA Symbols

Charts with only those pictures proven to be both recognizable and accurate are used. Research comparing the pictures with Snellen optotypes has shown a high correlation and thus an accurate acuity. A matching card helps shy or under-confident children. Other picture identification tests include the Allen test and LEA symbol tests for slightly older children which consist of various pictures of progressively decreasing size on a snellen like chart projected at a distance.

Sheridan Gardiner

Traditionally, it consists of single letter optotypes. The test is a matching test designed for use with children but is

also suitable for use with those with learning difficulties or with patients who do not share a common language with the examiner. The drawback of this test was an overestimation of acuity in amblyopic children and therefore now a modified test with linearly arranged alphabets is available.

Glasgow Acuity and Cambridge Crowding Cards

A significant 'crowding effect' has been found in children between the ages of three and six years and in amblyopes. Test based on single optotypes are not sensitive to amblyopia as linear optotypes, owing to the absence of contour interaction. In the glasgow acuity cards, a surround box is placed half a letter width away from the single test optotypes to improve the test sensitivity while in the Cambridge crowding cards, there is a central letter in a five letter array (with varying spaces) which needs to be identified.

HOTV test

The HOTV test is a letter matching test used in children who have difficulty in naming letters. In this, they have to match the letters shown to them at a distance with the matching cards in their hands. The test initially included only four letters H, O, T, V but has been expanded in the Sheridan test to include X, A, U, L and C also.

Bottom Row (Left to right): Sheridan Gardiner; Cardiff cards; Allen picture test; Snellen 'E' and alphabet chart

STYCAR

The STYCAR group of tests are sight tests for young children and retards. They consist of stycar balls test where small balls are attached to sticks of varying lengths to see up to where a child can see. Also the graded balls test and miniature toys tests work on similar principle. The STYCAR letters test consist of single or multiple letters from the Sheridan test which are to be matched by the child. These letter tests have similar value as the direction identification tests.

Snellen Charts and the LogMAR Chart

These are the most common performed visual acuity test in adults and most visual acuity is compared to Snellen equivalents. The charts are easy to read and quick assessment of visual acuity can be made. There are various types of charts such as the tumbling E or C charts for children who don't yet know the alphabets and the alphabet chart for those who are school going. Normally, the Snellen chart is read at a six metres distance and the normal visual acuity is 6/6. However, the Snellen chart does have few drawbacks such as a nongeometric pattern of letter size reduction or the absence of crowding phenomenon in the larger optotypes. These drawbacks are overcome in the LogMAR chart which has the same number of letters in each row and the letter sizes decrease in a strict

geometric progression leading to an accurate measurement of change.

Near Vision Charts

Near vision in children is very important since a child's visually stimulating world is very close to him/her. Though most of the above mentioned methods actually measure near or intermediate distance acuity, various specialized near vision charts are available. These include snellen near vision chart, jaegers chart among many others.

COLOR VISION

While neonates and young infants possess some ability to distinguish colors, it is inferior to that in adults. The eye starts to recognize colors around two to six weeks of age and this ability matures by around the age of four to six months. Assessing color vision perception in infants is difficult and possibly inaccurate and often they are attracted by the brightness and contrast of the object rather than by its color; therefore simply assuming that because a child is preferentially looking at colored objects is an improper way of assuming normal color vision. The most common chart used to assess color vision is the Ishihara chart which consists of numbers or lines made of colored dots which are surrounded by more such dots of a different color. On the basis of the child's ability to correctly read the number or trace the lines, color vision is reported to be normal or abnormal. Special charts similar to the classic Ishihara chart are available for children where shapes replace the numbers and lines, thus making it possible to test even smaller children. Other tests such as the Farnsworth Munsell or 100-Hue test are more cumbersome and possible only in the older children. Besides these, there are many online child friendly tests now available. If there is a family history of color blindness or parents suspect the same then the child should undergo a screening at least once prior to entering nursery since his learning may get significantly affected if the teachers and parents remain unaware and do not modulate their teaching methods.

CONTRAST SENSITIVITY

Contrast sensitivity has been described to be the single most complete measurement of spatial vision with a higher predictably of visual dysfunction than visual acuity alone. However, it requires special testing charts and equipment and limited normative data is available for younger children. It is generally been seen that the contrast sensitivity function rapidly develops between 6 and 12 weeks of age and then develops slowly to reach adult levels around 9 to 12 years of age.⁴ Ophthalmologists would usually perform contrast sensitivity testing using either a Pelli-Robson chart or a FACT chart in cases where retinal or optic nerve

dysfunction is suspected. There is no indication of doing regular screening of contrast sensitivity function.

VISUAL FIELDS

Visual field refers to the area in space the eye can see. It is determined and limited by the placement of the eye in the confines of the bony orbit. The visual field is often affected in many ocular conditions which impact the retina or optic nerve as well as in cortical dysfunctions. While a clinical assessment of visual fields can be done by finger-play or a confrontation test, objective/quantitative evaluation requires either a kinetic perimeter (Goldmann perimeter) or a static perimeter (Humphrey perimeter). Children frequently have difficulty in performing a fields test since it requires them to maintain a central fixation for an extended period of time. Therefore, visual field reports are often fallacious and need careful interpretation. The interactive protocols in automated perimetry enable faster testing as well as newer game based visual field testing are likely to be more reliable.

STEREOPSIS

Stereopsis refers to the ability to perceive depth and is a higher cortical function which depends on the presence of symmetrical good visual acuity of both eyes and normal binocularity. It is subnormal or absent in cases of amblyopia and strabismus and requires to be screened in only those cases. The normal value is 60 seconds of arc or better. It may be tested for near using various tests including Titmus fly test, Randot test, TNO test, etc. or for distance using distant Randot or Frisby-Davis (FD2) tests.

ELECTROPHYSIOLOGY

Electrophysiology of the eye includes visual evoked response (VER), electroretinogram (ERG) and electro-oculogram (EOG) which can determine the integrity of the visual system, retina and retinal pigment epithelium respectively. These tests require highly specialized equipment and are reproducible even in somewhat uncooperative children. Visual evoked response (VER) as a tool to assess visual acuity has been discussed above but besides that, its main utility is to determine whether the visual pathway extending from the retina and optic nerve to the occipital cortex is intact and functioning optimally. Pediatricians may often come across VER reports in terms of amplitude and latency which they should be able to grossly interpret. Though each laboratory has their own range of normal values, generally speaking amplitudes less than 8 to 10 microvolts and latency longer than 110 ms should be considered as subnormal. The interpretation of ERG and EOG are best left to the ophthalmologists and require clinical correlation.

OCULAR SCREENING IN CHILDREN

Pediatric ocular conditions are often silent and since children are often unable to express themselves regarding a poor quality of vision or low visual acuity, it is pertinent to screen them. While a large number of ocular afflictions are known in children, well defined screening protocols are established for only a handful of the sight threatening ones.^{6,7} The pediatrician is the first contact of the children and is therefore the ideal channel for an opportunistic screening of ocular diseases (Table 3).

Screening of the Neonate

The attending neonatologist should screen the newborns' eyes for any evidence of discharge or matting suggestive of ophthalmia neonatorum and also for any obvious ocular malformations such as cryptophthalmos, anophthalmos, etc. The neonatologist should also be alert to the fact that large appearing or hazy appearing corneas can be an indication of congenital glaucoma and need immediate evaluation by the ophthalmologist.

Screening for Retinopathy of Prematurity (ROP)

The American Academy of Ophthalmology and Pediatrics suggest a screening fundus examination for all infants born weighing 1500 g or less or with gestational age of 28 weeks or less and also for any premature infant weighing up to 2000 g, believed to be at risk by the attending pediatrician (has received supplemental oxygen or has an unstable neonatal course). The examination should be done 4 to 6 weeks from birth, or by 31 to 33 weeks postconceptional

age, whichever is earlier. Screening criteria formulated according to Indian scenario include screening all infants with birth weight less than or equal to 2000 g or those born at gestational age of less than or equal to 35 weeks.

Preschool Vision Screening

There are varying reports from literature about the need, correct age and screening test to screen for refractive error, amblyopia and strabismus in preschool children. Amid all the controversies, the American Academy of ophthalmology has defined the need to perform preschool vision screening at 3 to 3.5 years age. This includes screening for amblyopia using the crowded LogMAR chart. Screening for strabismus using the cover uncover test and screening for any refractive errors. While photostereopsis and use of autorefractors is commoner in the west, such a practice is nearly non-existent in India. An important question regarding who should screen also exists and various countries have differently recommended orthoptists or optometrists or trained lay people to perform the screening. In India, though not formally introduced, such screening is most likely going to be performed by the ophthalmic assistants and optometrists under the vision 2020 initiative.

School Screening

School screenings are being carried out under the national program for control of blindness and Vision 2020. School teachers are trained to assess and document visual acuity and all children with visual acuity worse than 6/9 are given

Table 3: Simple screening methods at various age groups and indications to refer to an ophthalmologist

Age group	Method/test	Ophthalmology referral if:
New born to 3 months	Inspection	Structural abnormality
	Red reflex	Abnormal or asymmetric
3-6 months	Red reflex	Abnormal or asymmetric
	Fix and follow light	Unable to fix or follow, abnormal movements
6-12 months	Red reflex	Abnormal or asymmetric
	Fix and follow	Unable to fix and follow, abnormal movements
	Alternate occlusion	Resists occlusion of 1 eye
	Corneal light reflex	Reflex not central in either eye
1-3 years	Corneal light reflex or cover-uncover test	Reflex not central in either eye; squint of eye
	Visual acuity (observation)	Unable to see small objects
	Head posture	If persistent and reproducible
	Activity (walking, coloring, etc.)	If holding objects to close or mixing colors
3-4 years	Cover uncover	squint of eye
	Visual acuity	If worse than 20/30 or two line difference between eyes
5 years	Visual acuity	If worse than 20/30 or two line difference between eyes
	School performance	Sits close to board or holds books too close to eyes.

glasses after refraction or referred if not improving after refraction. This is a successful model and is being increasingly implemented in various public schools.

Screening for Other Ocular Conditions

There is no defined screening protocol to look for conditions such as retinoblastoma, cataract, retinal dystrophies or glaucoma, etc. and it is probably not feasible to separately screen for each of these diseases. On the other hand, opportunistic screening such as when the child visits the doctor or during preschool and school screening may be the only way when such conditions can be looked for.

Special Conditions Requiring Screening

Children with juvenile rheumatoid arthritis need to be screened for anterior uveitis as this is usually silent and sight threatening. Since, the eye disease can precede the joint involvement, the first examination should be done after one month of diagnosis of JIA. The maximum likelihood for ocular involvement is four years after the onset of arthritis.

Children with Type I diabetes mellitus should be screened five years after the onset of diabetes and annually thereafter for retinopathy. If the child is older than nine years, the first ophthalmic examination should be done three to five years after diagnosis.

Color vision screening should be done in the preschool age for children who have a positive family history of color blindness.

SUMMARY

This chapter focuses on five common diseases in the field of pediatric dermatology, namely, atopic dermatitis, acne vulgaris, vitiligo, molluscum contagiosum and warts. We present an overview of these entities highlighting the recent advances in literature both in pathogenesis and management. An attempt is made to identify and emphasize novel treatment modalities that are especially suitable for the pediatric population. We believe the information contained herein will be of value to pediatricians who frequently manage these dermatologic conditions.

UPDATE ON PREADOLESCENT AND ADOLESCENT ACNE

Acne vulgaris is a common dermatologic disorder affecting 28 to 61 percent of the population in the age group 10 to 12 years and 79 to 95 percent between 16 to 18 years of age. The pathogenesis of acne is multifactorial and includes four key factors, namely:

1. Excess sebum production
2. Ductal hypercornification in sebaceous follicles
3. Colonization of sebaceous follicles with *Propionibacterium acnes*
4. Inflammation.

Acne in preadolescents and adolescents differs from that in adults in several ways. In the former groups the sites of predilection are forehead, nose and paranasal areas, and cheeks (upper face). With advancing age there is a cephalocaudal progression and in postadolescents and mature adults acne tends to involve more of lower face (Table 1). Further, whilst adolescent acne shows a mix of comedones and inflammatory lesions (acne vulgaris meaning common acne), in preadolescents it tends to be mostly comedonal and in adults it is inflammatory. Acne is more difficult to treat in preadolescents partly because

of compliance issues and partly because of a tendency on the part of the treating physician to employ suboptimal therapies. Also, onset of acne in preadolescents portends a more severe disease in ensuing years.

The success of acne management depends on careful evaluation of each patient for each of the pathogenetic factors, the anatomic distribution, and the number and type of lesions. The morphology of acne lesions is perhaps the most important parameter for choosing treatments (Table 2). The acne treatment is a program that is highly individualized and also takes into account the logistics and the motivations.

Role of *Pityrosporum* in Adolescent Acne

Pityrosporum orbiculare, (also known as *Malassezia furfur*) is a lipophilic yeast that colonizes the follicles in preadolescent years (along with *P. acnes* and *Staphylococcus epidermidis*). Although it is a commensal, it sometimes overgrows and turns pathogenic and causes seborrheic dermatitis. In teenagers, *P. orbiculare* occasionally produces papules and pustules in seborrheic distribution (central face, forehead, nasolabial folds, perioral area, sternal area, upper back and shoulders) mimicking acne. Termed *Pityrosporum folliculitis*, this entity tends to occur most commonly at the onset of puberty due to the activation of the sebaceous glands. *Pityrosporum folliculitis* may coexist with acne vulgaris. If unrecognized it can get aggravated by the use of antibiotics. What is even less recognized is that *P. orbiculare* may directly contribute to acne pathogenesis? This appears to be a tropical phenomenon more at play in the preadolescent population. Its pathogenetic role in acne is suggested by concomitant seborrhea capitis (dandruff), distribution of lesions along the frontal and temporal hairline, on the glabella and paranasal areas, predominance of papules and pinhead sized pustules, and a lack of response to antibiotics. If suspected, the acne

Table 1: Acne patterns in different age groups of patients

<i>Acne type</i>	<i>Pattern</i>	<i>Type of lesions</i>
Preadolescent	Forehead and paranasal areas	Comedones
Adolescent acne	Forehead, temples, malar area, cheeks, chin	Comedones, papules, pustules
Adult	Jawline, perioral	Mostly papules

Table 2: Spectrum of efficacy of topical agents in acne treatment

<i>Decrease in comedones</i>	<i>Sebosuppressive</i>	<i>Antimicrobial</i>	<i>Anti-inflammatory</i>
Tretinoin	++	-	-
Isotretinoin	++	-	+/-
Adapalene	++	-	+
Tazarotene	++	-	+/-

Erythromycin	+/-	-	++
Clindamycin	+/-	-	++
Benzoyl peroxide	+	-	+++
Salicylic acid	+/-	-	-

treatment program must include antifungal agents such as miconazole (topical gel), ketoconazole (shampoo), and itraconazole (orally).

Diet and Acne

The role of diet in the causation of acne (hitherto denied) has been resurrected. A large retrospective, cohort study reported that excessive intake of milk during adolescence was associated with more acne. Interestingly, this association with acne was more marked for skim milk than other forms of milk suggesting that the fat content of milk was not the reason. It was hypothesized that the hormone content of milk (estrogens, progesterone and androgen precursors) and the presence of bioactive molecules such as insulin-like growth factor-I (IGF-1) were the likely reasons.

Adolescents in westernized societies may be repeatedly hyperinsulinemic due to their high glycemic diet. Hyperinsulinemia in turn may initiate an endocrine cascade that affects the sebaceous gland and follicular keratinization through the involvement of IGF-1, IGFBP-3 (insulin growth factor binding protein-3), androgens, and retinoid signaling pathways, thereby causing hyperandrogenism and acne. This has been substantiated through studies demonstrating that diets rich in low-glycemic load foods reduced serum concentration of testosterone and increased levels of SHBG (Serum hormone binding globulin). Hyperinsulinemic diets, therefore, may represent a previously under-recognized environmental factor in the development of acne indirectly through androgen

Table 3: Mechanism of action of available treatment modalities

Benzoyl peroxide	Antimicrobial weakly comedolytic
Topical retinoids	Comedolytic Anti-inflammatory
Topical antibiotics	Antimicrobial
Systemic antibiotics	Anti-inflammatory (primarily) Antimicrobial
Oral contraceptives	Sebosuppressive
Systemic retinoids	Comedolytic Anti-inflammatory Sebosuppressive Antimicrobial (Indirectly)

mediated sebum production and alteration of follicular keratinization.

Enough evidence now exists in the literature highlighting the association of acne and high glycemic loads, certain dairy products and ingestion of refined sugars.

Management

Acne can persist for years and its long-term ramifications can be significant. Early and effective treatment is essential to avoid the physical and psychological scarring it may cause. The following considerations are important for successful management of acne:

- Customized skin care
- Individualized treatment program

- Adequate treatment duration
- Post-treatment maintenance.

The spectrum of efficacy of the topical agents used in the treatment of acne is illustrated in Table 2.

Of these, topical retinoids are the mainstay in the treatment of preadolescent and adolescent acne. They inhibit the formation of and reduce the numbers of comedones (primary lesion of acne), promote normal desquamation of the follicular epithelium and enhance the penetration of other drugs. A newly recognized function of topical retinoids has been their anti-inflammatory action through modulation of the immune response (Table 3).

The consensus recommendations for the use of topical retinoids are as follows:

- They should be the primary treatment for most forms of acne
- Use early for best results
- Apply to the entire affected area and not just the lesions
- Combine with antimicrobials in inflammatory cases.

A concern with the use of antibiotics in the treatment of acne has been the emerging resistance of *P. acnes* to the various antibiotics being used. A report from the 'Global alliance to improve outcomes in acne' emphasizes certain precautions while prescribing antibiotics in order to prevent antibiotic resistance. These are:

- Use oral antibiotics when topicals are not enough
- Withdraw antibiotics as soon as possible
- When repeating choose the same antibiotic
- Use benzoyl peroxide in combination to eliminate resistant strains
- Avoid concomitant dissimilar topical and oral antibiotics.

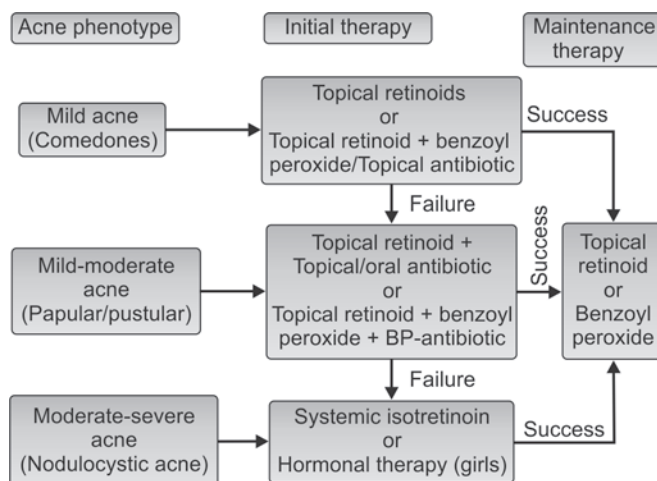

Because of the multifactorial nature of the pathogenesis of acne, a combination of different classes of drugs that affect different areas of pathophysiology should be used. No single therapy is able to counter all the four factors involved in the pathogenesis of acne.

A simple algorithm for the effective management of preadolescent and adolescent acne is illustrated in Flow chart 1.

ATOPIC DERMATITIS—A DERMATOLOGIST'S PERSPECTIVE

Atopic dermatitis (AD) is a chronic inflammatory skin condition with impaired cell-mediated immune function and compromised skin barrier. It is characterized by erythema, edema, vesicles and oozing in the acute stage and thickening and hyperpigmentation (lichenification) in the chronic stage. Approximately 70 percent of cases of atopic dermatitis start in children under 5 years of age. Asthma develops in 70 percent of the cases and allergic rhinitis in 35 percent. About 40 percent of children with AD are

Flow chart 1: Treatment of acne

free of symptoms by early adolescence although up to 50 percent may have recurrences in adulthood.

The severity scales used in clinical trials are generally not suited for rapid assessment in the clinic. Parameters such as presence or absence of sleep disturbances, number and location of involved sites, and the clinical course are suitable indicators of severity and provide the best basis for making decisions about treatment. Skin biopsy is of little value in the diagnosis of AD. It is important to keep in mind that early-onset disease, severe early disease, concomitant asthma and allergic rhinitis, and a family history of atopic dermatitis may predict a more persistent course.

Etiology

Atopic dermatitis (AD) is a complex disease relying on an inter-play of several factors. Many genes have been identified over the years; however, genetics alone cannot explain the rising prevalence of AD in some countries. Current epidemiological research has suggested a key role of the environment in mediating disease expression. Allergens such as house-dust mite and certain foods may also be important in addition to *Staphylococcus aureus* infections, exposure to heat and to irritants that disrupt the skin barrier.

Atopic Dermatitis and the "Hygiene Hypothesis"

Atopic dermatitis (AD) is more common in urban than in rural communities and more prevalent in western industrialized countries than in developing countries. It is also shown that AD is more in children growing up in smaller families and families of higher socioeconomic status therefore it has been suggested that the disease is more likely to occur when the developing immune system is deprived of the obligatory stimulation through certain nonpathogenic microbial antigens. This hypothesis has prompted the use of probiotics such as *Lactobacillus* GG supplementation as a new

therapeutic approach towards treatment of AD although sufficient data is unavailable to substantiate their efficacy.

Management

The treatment of atopic dermatitis involves a combination of preventive measures aimed at suppressing the symptoms of disease and individualized treatment for controlling and preventing recurrences. The successful management requires a multipronged approach.

Breastfeeding and Diet in Atopic Dermatitis

It has been shown that exclusive breastfeeding during the first-three months of life is associated with lower incidence rates of atopic dermatitis in children with a family history of atopy. This effect is lessened in the general population and negligible in children without first-order relatives. Therefore, breastfeeding should be strongly recommended to mothers of infants with atopy in the nearest family as a possible means of alleviating or even preventing AD. Since this is not the case in children without such history for whom breastfeeding is recommended for its other multiple benefits. Avoiding foods suspected to cause flares may be helpful in young children with severe disease. However, there is little evidence to support dietary exclusion of milk and eggs in unselected cases except for infants with AD who produce IgE antibodies to egg proteins in whom egg-free diets before the age of 2 years may be of benefit.

Topical Corticosteroids

Topical steroids have been the mainstay of treatment of AD for many years. They are chosen on the basis of their potency which is determined by their potential for vasoconstriction—a surrogate for clinical efficacy and skin thinning. In general, topical steroids of mild and moderate potency are used on the face and genitals (where the skin is thin), whereas, those of moderate to potent strength are used over other areas of the body. However, in the pediatric age group low potency steroids may be sufficient for use in all areas of the body and only in chronic AD (lichenified lesions) should higher potency steroids be used.

Reduced efficacy of topical steroids has been an area of concern in AD but it is important to remember that this may be related more to inappropriate use of the steroid in relation to disease severity rather than steroid resistance or tachyphylaxis. With the advent of newer preparations of topical steroids (like mometasone) once daily application have proven to be as effective as twice daily or more frequent applications thereby minimizing the risk of local side-effects. It is also essential while treating AD that the topical steroids be used for an adequate duration (up to few days after clinical clearance as assessed by the parents of children being treated) rather than intermittent use of

steroids for the fear of side-effects that results in partial clearance of lesions with more frequent recurrences.

Topical Calcineurin Inhibitors

Tacrolimus, the prototype of this category of drugs, is a nonsteroidal topical immunomodulator now used for the treatment of AD with the advantage of having efficacy similar to topical corticosteroids (gold standard for the treatment of AD) in addition to an excellent safety profile. Tacrolimus inhibits T-cell maturation and activation by the inflammatory cytokines through the blockage of calcineurin action, an important mediator of cytokine release. Topical tacrolimus is available in an ointment base of two strengths -0.03 and 0.1 percent. The lower potency of 0.03 percent is preferred for application on the face and genitals and the 0.1 percent over other areas of the body. Topical tacrolimus 0.1 percent ointment has shown to be similar in efficacy to midpotency topical steroids and it may be used alone or in combination with steroids. Tacrolimus offers the advantage of not causing skin atrophy or telangiectasia despite prolonged use as compared to its steroid counterpart. Five-year studies have shown a good safety profile with the only side-effect being mild burning sensation at the time of first application that clears with subsequent use. There has been some concern about the increased risk of infection with the use of topical tacrolimus in AD due to local suppression of the immune system, however, studies have shown that the risk of infection (bacterial or viral) either remains the same or reduces with continued use of tacrolimus. It has been indicated that the lower incidence of cutaneous infections in long-term studies could be related to sustained improvement in AD (with associated improvement in the skin barrier function) with extended use of tacrolimus. In addition, it has been reported that topical tacrolimus significantly reduces *Staph. aureus* colonization in AD lesions (responsible for exacerbation in majority of AD cases) and specifically blocks the release of *S. aureus* superantigen induced T-cell proliferation in AD.

Pimecrolimus is the more recent member of the calcineurin inhibitors available in USA in a cream formulation as Elidel® but not available in India as of now. It targets T-cells and mast cells by inhibiting the production of cytokines and other inflammatory mediators essential for the activation of these inflammatory cells. In contrast to corticosteroids, it does not affect Langerhans cells or fibroblasts and therefore does not have any inhibitory effect on collagen synthesis eliminating the most infamous adverse effect of skin atrophy seen with the use of topical steroids. Pimecrolimus differs from its contemporary tacrolimus in the following ways:

- It is available in a cream formulation as opposed to the ointment form of tacrolimus

- More suited for application around the eyes
- Permeates through the skin less than tacrolimus resulting in less transcutaneous absorption after topical application thereby having less potential for systemic effects when used over a large surface area
- High anti-inflammatory activity and theoretically more favorable balance of anti-inflammatory versus immunosuppressive activity than tacrolimus.

In March 2005, the US FDA issued an alert to all health-care professional concerning a potential link between topical pimecrolimus and tacrolimus and cancer (mainly lymphoma and skin cancers) on the basis of studies in animals, and case reports, and the current knowledge of how these drugs work. The alert emphasizes the importance of using these preparations in children above 2 years of age, when first-line treatments have failed or cannot be tolerated, and advises intermittent and short courses. Although, recently there has been data in the literature that does not support these concerns and propagates the use of the topical calcineurin inhibitors in patients with atopic dermatitis in whom topical corticosteroids cannot be employed for the fear of causing irreversible side-effects. These calcineurin inhibitors have provided a fresh approach to the chronic management of this frequently relapsing disease and although their long-term safety (greater than 5 years) is not yet established their judicious use and surveillance can avoid problems.

Role of Antihistamines

Because both atopic dermatitis and asthma are treatable but not curable conditions, the development of strategies for prevention of the diseases has a high priority. AD is a common precursor to the development of asthma and it was suggested that the use of an H1-antagonist might reduce the development of asthma at least in subgroups with evidence of high IgE levels. Thus, the early treatment of atopic child (ETAC) study was conducted to establish whether the intervention merely suppressed symptoms or truly prevented disease. The ETAC study was a double-blinded, parallel-group, randomized trial of 0.25mg/kg body weight cetirizine administered twice daily compared to placebo in children between the age group of 1 to 2 years with AD for a study period of 18 months and a follow-up period of another 18 months. The study concluded that cetirizine compared to placebo truly delayed or in some cases prevented the development of asthma in a subgroup of infants with AD sensitized to grass pollen or house-dust mite.

Subsequently, a multicountry double-blinded, randomized, placebo-controlled trial called the ETAC trial was done for a study period of 18 months to analyze the effect of long-term use of cetirizine on the severity, natural history and treatment of AD. The study showed that the severity of AD decreased significantly over the study

period of 18 months in both groups (placebo and cetirizine 0.25 mg/kg twice daily) but the use of other supportive treatment for AD like topical corticosteroids and oral antihistamines was significantly reduced in the cetirizine group. The study also showed that the duration of use of topical steroids was reduced in the cetirizine group and this steroid-sparing effect was statistically significant.

In view of the proven safety of cetirizine, it was suggested that the use of this drug might help to reduce the duration and amount of topical steroids used in the treatment of AD in infants although further studies are needed to confirm if the use of oral antihistamines can alter the natural history of the disease. In the experience of the senior author (RK) once daily use of an oral antihistamine like cetirizine over an extended period of time (6 months to 1 year) is rewarded with fewer relapses and acute exacerbations and this is likely linked to a drop in total IgE. Also, such an extended treatment is devoid of toxicity or tachyphylaxis.

CHILDHOOD VITILIGO

Vitiligo is an idiopathic disorder characterized by depigmented macules that result from the destruction of melanocytes. The disease is cosmetically disfiguring and may produce a profound psychological impact due to the associated social pressures. Vitiligo affects between 1 to 2 percent of the world population; however, the prevalence in India is about 2.5 percent. The onset of the disease in about 50 percent of the affected people is before the age of 20 years with a peak between 4 to 8 years, thus making vitiligo an important pediatric problem.

The clinical presentations may vary and include generalized (most common), segmental and acrofacial types. Segmental vitiligo of childhood tends to be less progressive than other types but reportedly is more recalcitrant to therapy.

Etiology

The current opinion on the causation of vitiligo favors the composite theory. There is a genetically determined defect either inherent to the melanocyte or in the melanocyte-keratinocyte signaling pathway that causes the defective melanocytes to accumulate excess of intermediate products in the melanin biosynthesis pathway. This leads to melanocyte apoptosis causing the release of cell-surface antigens from these dead melanocytes that in turn sensitize the immune system resulting in the formation of antibodies and cytotoxic T-cells. Eighty percent of vitiligo patients have melanocyte autoantibodies and the level of these antibodies is directly proportional to the disease activity and severity.

Although majority of the cases of vitiligo are idiopathic, there is a subset of individuals who have 'chemical

leukoderma' (morphologically indistinguishable from true vitiligo). Chemical leukoderma has been documented to occur following exposure to certain chemicals, the most common being phenolic compounds with catecholic derivatives. Many have been demonstrated to be preferentially cytotoxic to melanocytes with high dose exposure resulting in apoptosis. There is an unsuspected presence of such potential chemical depigmenting agents in solid rubber as phenolic derivatives are used as rubber additives and for hardening of rubber. Day-to-day exposure to such depigmenting chemicals can come from everyday use items like rubber footwear. Such individuals with a genetic disposition may then develop depigmentation at the site of contact (soles with sparing of the insteps) and the depigmentation spreads beyond the area of contact, probably via an immune-mediated mechanism. It is at this stage that the disease is recognized and often mistaken for true idiopathic vitiligo. However, if the causative agent is not avoided (rubber footwear) the disease becomes resistant to treatment or the response to the treatment is slow (personal observation of the authors).

In some cases, especially in the early part of the disease, when the lesions appear hypopigmented as opposed to depigmented the diagnosis may be questioned. In such cases, the use of Wood's lamp (ultraviolet of 365 nm) is extremely helpful. If a given lesion accentuates under Wood's light it indicates the complete loss of pigment and the diagnosis of vitiligo can be made with considerable certainty. In few cases, however, a histopathological assessment through a skin biopsy may be needed to confirm the diagnosis.

Management

There are certain considerations to be kept in mind while planning the treatment of vitiligo. It is important to keep in mind the duration of disease, disease activity and extent of depigmentation. The following are the aims of treatment:

- Arresting disease activity by preventing further damage to the melanocytes
- Repigmenting the depigmented lesions by stimulating melanogenesis in the residual melanocytes
- Attempting to modify the natural course of disease by adequate control at the appropriate time.

For the past two decades, monotherapy with topical steroids has been the most common treatment for vitiligo in children. Topical steroids are most effective in small newly depigmented areas. They work by limiting the amount of antimelanocyte autoantibodies produced locally. However, the risk of cutaneous atrophy and telangiectases, especially on the face and intertriginous areas in addition to the ocular side-effects secondary to periorbital application precludes their use over extended periods of time. It is for this reason that tacrolimus, a macrolide immunosuppressant is now being used as a novel treatment for vitiligo.

The effectiveness of topical tacrolimus in treating vitiligo may stem from its suppression of autoantibody recognition of cell-surface melanocyte antigens and inhibition of subsequent cytotoxic T-lymphocyte reactions.

Tacrolimus is used topically in the concentration of 0.03 percent on the head and neck and 0.1 percent over the trunk and extremities as once or twice daily applications in children over 2 years of age. Repigmentation over the head and neck is greater and quicker than over the trunk and extremities with the eyelids responding most rapidly and quickly. As seen with topical steroids, tacrolimus does not have any side-effects of atrophy, telangiectases and striae even after extended use. The adverse effects are minimal and limited to mild initial burning at the site of application that resolves with subsequent applications. Tacrolimus is a particularly welcome agent for the recalcitrant group of patients with segmental vitiligo, especially on the head and neck. There has been some suggestion in the recent literature that UV light and tacrolimus ointment in combination may be superior to tacrolimus alone, however UV light is not necessary for the beneficial effect of the drug.

Tacrolimus ointment has limited absorption from the vitiliginous skin and so no significant blood levels have been detected even when the drug is applied over large areas of the body. Tacrolimus has not been found to be phototoxic, photoallergenic or photosensitizing that further establishes its safety for use over depigmented skin. Given its immunomodulatory properties and safety profile, tacrolimus provides a new therapeutic alternative to steroids for the treatment of localized childhood vitiligo.

Management of Active Childhood Vitiligo

Role of Levamisole

Levamisole is an antihelminthic drug with immunomodulatory properties that has been used for the treatment of vitiligo for many years. It is used in children in the dose of 50 mg to 100 mg/day on two consecutive days in a week for 6 months to a year in slowly or equivocally progressive disease. There has been limited data to substantiate the efficacy of levamisole in controlling disease activity and the few studies done show varied results in marginally active vitiligo. Levamisole has limited side-effects like altered taste sensation and nausea. Agranulocytosis, though documented is extremely rare. In view of its potential efficacy and excellent safety profile, levamisole offers to be an additional tool in the armamentarium of the treating physician.

Oral Corticosteroids

Use of oral steroids as oral minipulse therapy (prednisolone 0.5 mg/kg dose on two consecutive days a week) is effective in arresting disease activity in patients with active/progressive vitiligo. This form of therapy is virtually

devoid of adverse-effects and there is sufficient data in the literature to support its safety even in children. Oral steroids in this form may be used for 6 months or more to arrest the disease and induce remission. In rare case where oral minipulse is unsuccessful, daily oral steroids (prednisolone 0.5 mg/kg for a period of 1 to 2 months is both effective and justifiable.

Immunosuppressants

When the parental concerns about the spread of disease are extreme and the social pressures abound then immunosuppressants have been used by the authors. This is reserved for special cases where oral steroids have not been able to adequately arrest disease activity but only after discussing the pros and cons with the parents of the children under treatment. Azathioprine, is the preferred choice of the authors with experience of over 10 years. The drug is used in a dose of 50 mg/day in children for a period of 6 months to a year. Due to the availability of the drug as 50 or 100 mg tablets, it is difficult to use the drug in the mg/kg dosage. Azathioprine works as a steroid sparing agent such that steroids can be discontinued sooner (within 6 months of starting treatment) and azathioprine continued for an extended period of time (senior author's experience) till the disease is rendered inactive. Azathioprine is a well-tolerated drug with rare side-effects. Before the initiation of therapy blood tests, urine analysis and a chest X-ray are done to rule out any latent infections. Also, immunizations are administered before the start of therapy and live vaccinations are avoided during the course of treatment. In the experience of the authors, no serious adverse effects or systemic toxicity has been observed in both new and follow-up cases and after many years of discontinuing therapy.

Summary

The face and neck respond best to all therapeutic approaches, while the acral areas the least. For generalized vitiligo, phototherapy with narrow-band UVB is the most effective with the fewest side-effects. PUVA is the second best choice. Topical steroids are the preferred drugs for localized vitiligo. They may be replaced by topical immunomodulators which display comparable effectiveness and fewer side-effects. The efficacy of vitamin D analogues is controversial with limited data. Surgical therapy can be very successful, but requires an experienced surgeon, limiting its widespread use. No single therapy for vitiligo can be regarded as the most effective as the success of each treatment modality depends on the type and location of vitiligo.

NOVEL TREATMENTS FOR MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum (MC), a common cutaneous viral infection in children is caused by a double-stranded DNA

pox virus. Published data estimate the incidence of MC to be 1.2 percent to 22 percent worldwide. The peak age of MC is between 2 to 12 years and the condition is highly transmissible in this population. The infection spreads via skin to skin contact, through fomites, and autoinoculation. It tends to be more common in children with atopic dermatitis, and in immunodeficiency states such as leukemias, posttransplantation, and HIV-infection. These associations suggest that a defective T-cell immunity may play a role in MC infection.

MC lesions are clinically distinctive and appear as pearly, translucent papules, a few millimeters in diameter, and usually show a depression or a dell on the summit. The lesions multiply rapidly, especially in areas of increased moisture and skin to skin contact such as axillae, groins, antecubital and popliteal fossae. Erythema, if noted, around the lesions signifies an inflammatory host response against the viral pathogen portends spontaneous clearing. MC frequently shows spontaneous clearing, however, this sometimes takes months to years.

Autoinoculation, superinfection, transmission of the virus to susceptible contacts, and cosmetic stigmata are some of the concerns for which parents request treatment. Available therapeutic options are destructive modalities such as manual curettage, cryotherapy with liquid nitrogen, and electrofulguration. Even though cryotherapy and manual curettage are very effective options their use in the pediatric population is limited by the pain associated with such treatments, and the possibility of scarring. Topical agents such as tretinoin cream are moderately effective but prolonged treatment time, inconsistent response, and the erythema, burning and pruritus associated with its use make it a less favorable option.

A relatively unrecognized effective topical agent that may be used for the treatment of MC is cantharidin. It is an extract of the blister beetle, *Cantharis vesicatoris*, a member of the *Mecoidae* family of arthropods. It is a protein phosphatase inhibitor that penetrates the epidermis and induces vesiculation. Since the poxvirus resides in the superficial layers of the epidermis the vesiculation disrupts the virus which is subsequently shed off together with the crust of the lesion after a few days. The use of cantharidin for the treatment of MC was first described in 1961 by Funt, but limited data and concerns for safety have tempered with widespread acceptance of this form of therapy.

Cantharidin is available in two forms:

- *Canthacur* 0.7 percent Cantharidin
- *Canthacur PS* 1 percent Cantharidin
5 percent Podophyllin
30 percent Salicylic acid

Canthacur is manufactured by *Pharmascience inc. for paladin labs inc.* Montreal, CANADA H4P2T4 (ordering information 1-888-376-7830/ 514-340-1112).

Cantharidin application is a clinic procedure and is not recommended for home use. It is extremely easy to apply and when done so in a consistent and controlled manner, it is devoid of any complications.

The main advantage of this form of therapy over others is that it is painless in addition to being effective and therefore, aptly suited for use in children.

Attention to the following practical details ensures success when using cantharidin.

- The blunt end of a toothpick is used for precise application of a tiny amount of cantharidin over each lesion avoiding contact with the surrounding normal skin.
- The site is allowed to dry for 2 to 3 minutes. If the fluid spreads it can blister the normal skin around the lesion as well.
- A maximum of 20 lesions may be treated per visit
- Parents are instructed to rinse off the treated areas with soap and water after 4 to 6 hours (or occasionally sooner if the child feels discomfort)
- Repeat treatment is done at 2 to 4 week intervals.

A small percentage of patients treated may experience transient burning or pruritus and rarely, pain on the day of the treatment which responds to a single dose of paracetamol. Vesiculation occurs on the second or third day followed by crusting after a week and then the scab falls off. The lesion resolves without scarring. No superimposed infection has been reported in the literature or observed by the authors. Cantharidin, therefore, is a very safe and effective monotherapy for Molluscum Contagiosum in children.

Another painless modality that may be used for the treatment of MC in children above 4 years of age, is imiquimod. Imiquimod, an imidazoquinolone derivative, and the prototype of a family of topical immune response modifiers, causes specific stimulation of a local antiviral response through the activation of both innate and cell-mediated acquired immune responses via induction, synthesis and release of specific cytokines from monocytes and macrophages. Imiquimod is available as 5 percent cream in small sachets (3-12 sachets per box). It is used as local application three times a week which may be increased to

daily application after 2 to 4 weeks. Since the product is light sensitive, it is advised to open each sachet with a pin-prick and store the rest in the refrigerator for subsequent use. This not only preserves the product but also makes it more cost-effective. Studies have shown resolution of majority of the lesions within 16 weeks of therapy with minimal to no recurrences. The most common adverse effect is erythema localized to some of the treated lesions. The outcome is clearance of the lesions with excellent cosmetic outcome compared to other painful and potentially scarring alternative therapies. No systemic toxicity has been reported making topical imiquimod application an antiviral and nondestructive treatment option for treatment of molluscum contagiosum presenting as a major therapeutic advance.

Since 1999, studies have been published that satisfactorily tested the use of potassium hydroxide (KOH) in different concentrations for the treatment of molluscum contagiosum but none compared these to placebo, a recent randomized control trial compared the efficacy of 10 percent and 15 percent KOH with placebo and demonstrated that KOH may be a good therapeutic alternative for the treatment of molluscum contagiosum as it is effective, easy to apply, self-administered, inexpensive, readily available and with minimal side-effects.

Amongst the numerous treatment modalities available for the treatment of MC, choosing the right treatment is often difficult. The effectiveness of therapy and the ease of administration are two key factors to keep in mind while treating children. We provide a summary of the painless yet effective options that are available for the treatment of MC in children (Table 4).

WHATS NEW IN THE TREATMENT OF EXTRAGENITAL WARTS

The prevalence of human papillomavirus (HPV) infection is continuing to increase globally. Subtypes of HPV associated with nongenital warts (verruca vulgaris, verruca plana, and verruca plantaris) include HPV 1, 2 and 3. Pediatric population is particularly susceptible to these

Table 4: Therapies for molluscum contagiosum in children

<i>Treatment</i>	<i>Advantages</i>	<i>Disadvantages</i>
“Watchful waiting”	Painless; no scarring	Potential for spread
Cryotherapy	Effective	Painful; multiple sittings
Curettage	Effective; immediate results	Painful; risk of scarring
Tretinoin cream	Readily available; inexpensive	Minimal efficacy; poor tolerance
Cantharidin	Very effective; painless	Restricted availability
Imiquimod cream	Effective; painless	Expensive; prolonged duration of treatment
Potassium hydroxide	Self-administered; inexpensive; readily available	Limited data to support efficacy and safety

infections that tend especially to be resistant to treatment in immunocompromised patients.

A variety of therapeutic modalities have been used in treatment of warts. These are mainly directed towards tissue destruction and include electrosurgery, cryotherapy, topical salicylic acid, topical and oral retinoids, and intralesional bleomycin, plus some newly available methods such as pulsed-dye laser. These modalities are either of limited efficacy (salicylic acid, retinoids) or are painful and, therefore, not appropriate for use in children. Warts in immunocompromised patients are notoriously persistent and often refractory to standard treatment. It is in this context that the use of imiquimod becomes valuable and attractive.

Imiquimod is the first member of a new class of drugs, the immune response modifiers, and is a potent stimulator of innate and cell-mediated immune pathways resulting in potent antiviral, antitumor, and immunoregulatory properties. Imiquimod, available as a 5 percent cream formulation, is currently approved by the US FDA as patient applied therapy for external genital and perianal warts and is safe for use in children aged 4 years and above. Multiple treatment regimens have been tried but it is recommended that it be used five times weekly for up to 16 weeks. The largest study to date reported beneficial effects in 56 percent of all patients treated with 30 percent achieving complete clearance and a greater than 50 percent reduction in lesion size in the remaining 26 percent. The response to imiquimod is better for warts located on the trunk, face or dorsa of hands compared to the feet possibly due to decreased penetrability of the drug through the thick keratin layer in acral areas. The adverse effects are few and minor, like – mild erythema and, rarely, erosions confined to the site of application. Imiquimod, therefore, is a new, safe, moderately effective option for the treatment of cutaneous warts with the distinct advantage of being painless (a major consideration when treating children). It is also an effective option for treatment of recalcitrant warts especially in immunocompromised patients.

Another pain-free treatment option (extensively discussed in the treatment of molluscum contagiosum) is cantharidin. This is particularly useful for the treatment of periungual warts in children. The formulation containing cantharidin with podophyllin and salicylic acid (CAN-THACUR PS) is especially suited for use in plantar warts that are either difficult to treat or are resistant to most forms of therapy. This treatment modality has the advantage of being a simple office procedure that offers an effective, safe and nontraumatic option for the treatment of warts.

Salicylic acid has been an option for home treatment of verrucae especially on palmoplantar areas for many years, however, its limited efficacy has made it more of an adjunct therapy usually in combination with other clinic treatments like cryotherapy. A recent trial of patients with

plantar warts showed no evidence of difference in clearance of verruca at 6 months between daily application of salicylic acid (50%) for 8 weeks and cryotherapy (4 treatments 2 to 3 weeks apart; 10 second cycle). Cryotherapy, however, was a more painful and more expensive treatment option between the two. This study has renewed the role of salicylic acid as a stand-alone treatment option for verruca, especially when a painless and inexpensive option is sought.

Kangaroo Mother Care

MMA Faridi, Veenu Aggarwal

INTRODUCTION

Poor child survival is still a major concern in India and other developing countries. Current neonatal mortality rate of 39 per 1000 live births accounts for approximately 2/3 of all infant deaths.¹ A closer look reveals that neonatal deaths are concentrated among preterm and low birth weight babies. There are five principles for newborn care.

- Maintaining temperature
- Practicing asepsis
- Providing nutrition- breastfeeding or breast milk feeding as the source of nutrition
- Monitoring of danger signs
- Appropriate follow-up.

The *in utero* temperature is 38°C and fetus spends considerable time there. At birth baby is drenched with amniotic fluid, has large surface area compared to body weight, experiences low environmental temperature, generally suited to adults, with large temperature gradient and soon starts losing heat. It has been estimated that a newborn baby loses about 0.1°C rectal temperature per minute losing about 1°C in 10 minutes. This equals to expenditure of 200 Calories. Thus, heat loss is accompanied by increased glucose consumption that may lead to hypoglycemia if heat loss is allowed to occur. Hypothermia has serious pathophysiological repercussions and increases the risk of mortality by 40 percent.

Breast milk is the natural and ideal food for the baby, and breastfeeding is the most preferred method of feeding the newborn that goes beyond providing nutrition, preventing infections, developing bonding with the mother, leaving imprints for better cognitive development and IQ, and ensuring quality survival. Early initiation of breastfeeding within one hour of birth has been shown to reduce neonatal mortality by 22.3 percent and if breastfeed can be started within 24 hours it can still prevent 16 percent neonatal mortality.

Sepsis neonatorum is the single most important cause of neonatal mortality. Health facility acquired infection is an important issue in the neonatal intensive care units world over. In developing countries financial and human resources for neonatal care are limited. Any simple, low cost, reproducible intervention for low birth weight (LBW) infants that can reduce neonatal morbidity and mortality would be an important advancement in the neonatal care. Kangaroo mother care (KMC) is one such effective and evidence based adjunct to conventional neonatal care.

WHAT IS KMC?

The KMC envisages a baby rearing method that has practical similarities to marsupial care giving where the premature infant is kept warm, insulated from external noxious stimuli and fed mother's milk ad libitum, in the pouch situated on the abdomen of the marsupial mother close to breast. The kangaroo mother, most famous member of marsupial species, makes herself an 'incubator' thus maintains temperature of the premature fawn and provides unhindered breastfeeding as the main source of food and stimulation. Kangaroo mother care (KMC) was first suggested by Rey and Martinez in Colombia in 1978. They showed beneficial effects of KMC in maintaining body temperature of the preterm and LBW newborn infants both in the hospital as well as in the community. Subsequent researches have proved that KMC is safe; effective in maintaining normothermia; encourages exclusive and prolong breastfeeding; improves child survival and helps in better cognitive development in both developed and developing countries.

Evidence of the effectiveness and safety of KMC is available only for preterm infants without medical problems, the so-called stabilized newborn. Research and experience show that:²

- Kangaroo mother care (KMC) is at least equivalent to conventional care (incubators), in terms of safety and thermal protection, if measured by mortality.
- Kangaroo mother care (KMC) by facilitating breastfeeding, offers noticeable advantages in cases of severe morbidity.
- Kangaroo mother care (KMC) contributes to the humanization of neonatal care and to better bonding between mother and baby in both low and high-income countries.
- Kangaroo mother care (KMC) is, in this respect is a modern method of care in any setting, even where expensive technology and adequate care are available.
- Kangaroo mother care (KMC) has never been assessed in the home setting.

HOW KMC WORKS ?

Kangaroo mother care (KMC) revolves around mother and baby togetherness. Baby's skin intimately touches mother's or other care giver's skin. Touch and temperature sensations exchange two ways. Following attributes, though more may be in store, can explain KMC.

Skin to Skin Contact

Naked baby with diaper is kept day and night, between the mother's breasts, with his abdomen firmly attached to her chest in upright position by a cloth (binder). Mother's body heat warms the baby and maintains normothermia. There is some evidence that maternal body temperature increases or decreases depending on the baby's body temperature. Thus, mother acts as a servocontrol heater.

Breastfeeding

Mother is able to do frequent and exclusive or predominant breastfeeding. Close proximity and SSC enhance oxytocin reflex that helps flowing breast milk from the lactiferous glands to the areola.

Bonding and Stimulation

Skin to skin contact (SSC) brings baby very close to mother. Movement of the chest and abdomen, and cardiac pulsations of the mother stimulate the baby and help in early maturation and prevention of apnea.

Enteromammary Circulation

Skin to skin contact (SSC) transmits and transfers commensal organisms from the maternal skin to the baby which helps in preventing colonization by harmful pathological bacteria. At the same time neonatal skin flora, that represents NICU/hospital pathological organisms, is transmitted to the mother who in turn makes antibodies against them. These antibodies are passed on to the baby

through breast milk and prevents development of the disease.

Olfactory Stimulation

Maternal pheromones produce individual smell and odour. Skin to skin contact (SSC) gives enough opportunity to the baby to 'sense and feel' her mother. It stimulates the baby and helps in development and better IQ.

Monitoring Danger Signs

Mother is intimately involved in the care. She can easily appreciate changes in the baby which may be pathognomonic like color change, lethargy, poor feeding, abdomen distension, vomiting, etc.

Confidence Building

Mother takes substantial charge of the newborn care. Her confidence boosts. Kangaroo mother care (KMC) gives her a sense of fulfilment that she can look after her pre-term and LBW baby and that she is important to her child as much as health workers. This morale boosting is very important for continuance of the care at home after discharge.

Early Discharge

Kangaroo mother care (KMC) has been credited with early discharge from the hospital. It saves money and risk of nosocomial infections.

BENEFITS OF KMC

The most important ones are promotion of exclusive breastfeeding and providing effective thermal control.

Other advantages are:

- Kangaroo mother care (KMC) prevents apnea by stimulation.
- Prevents nosocomial infection.
- Prevents exposure to nursery noise and bright light.
- Improves maternal and infant bonding
- Provides satisfaction and builds confidence in mother in care of delicate LBW baby.
- Cheap but equally effective, convenient substitute of expensive conventional neonatal care.²
- Early discharge from hospital.
- Diminishes pain during painful procedures in sick LBW babies.³

KMC LOGISTICS

K=Knowledge, skills, setting, communication

M=Money, manpower; machines, management, monitoring

C=Care for feeding, comfort, confidence

K = Knowledge, Skills, Setting, and Communication

The success of the KMC depends upon the counseling skills of the health givers. After initial stabilization of the baby in the NICU/health facility, nurse/physician must talk to the mother and family including father about KMC. Let mother understand advantage of thermal control and of breastfeeding or breast milk feeding in the care of the newborn baby. She then is introduced about the concept of KMC and how it maintains temperature and helps in breastfeeding. Once mother is confident and willing to undertake KMC, then nurse may give some 'practical help' by positioning the baby between breasts of the mother for 30 to 60 minutes and be supportive to her in the beginning. Later on KMC sessions may be prolonged to 6 to 8 hours and even to 24 hours.

Kangaroo mother care (KMC) can be implemented at different levels like small maternity facilities which lack special equipment (incubators, warmers). If possible LBW babies who are sick should be referred otherwise KMC can be implemented if a skilled health worker is available. Kangaroo mother care (KMC) can be provided in the following situations:

- Hemodynamically stable baby
- Birth weight >1.8 Kg—Usually stable, if so initiate soon after birth
- Birth weight 1.2 - 1.79 Kg—If stable, may initiate at home. If needing referral then while transporting baby can be kept in continuous skin to skin contact with the mother. In hospital KMC can be initiated after stabilization.
- Birth weight <1.2 kg—After delivery they usually develop serious prematurity related complications. Kangaroo mother care (KMC) can be initiated only after hemodynamic stabilization along with ongoing O₂, iv fluids or tube feeding.

M = Money, Manpower, Machines, Management, Monitoring

In general no equipment or elaborate arrangement is required to do KMC. All mothers irrespective of parity, age, education, religious affiliations or working status can provide effective KMC. However, it is important that place where KMC is being given should be clean and comfortable and secure to maintain privacy. The room temperature should be 22 to 24°C; low noise level, reclining chairs, bed with adjustable backs or ordinary beds with extra pillows; reading material and free access to father/family members.

Mother can wear any clothing that pleases her but whatever she wears it should accommodate the baby firmly and comfortably in contact with her skin. The garment shouldn't be too tight. The support binder (carrying pouch), is the only special item needed for KMC which helps mother holding baby safely close to her chest. To begin with, use a piece of cotton cloth, about a meter

square, folded diagonally in two and secured with a safe knot or tucked up under the mother's armpits. This leaves mother with both hands free and allows her to move around and do routine work while carrying the baby on to her chest.

Baby is placed naked except diaper, woollen cap and socks. If room temperature drops below 22°C, she should wear a cotton, sleeveless shirt, open at front to allow her face, chest, abdomen, arms and legs to remain in skin contact with mother's chest and abdomen. Then mother covers herself and the baby with her usual dress.

It is very important that mother maintains hygiene. It should be explained to her that she should take bath and change clothes daily. She should wash hands with soap and water each time she uses toilet. Diaper should be changed at least 4 hourly if wet and soiled. Baby's bottom may be cleaned with warm water. There is no need of using dettol or any other antiseptic-mixed water for bottom cleaning.

Mother should manually monitor body temperature of the baby by touching his abdomen and then his feet by back of her hand. Ideally both should be warm.

C = Care for Feeding, Comfort, Confidence

Breastfeeding should be done on demand when she feels that baby is trying to suck on the breast. Else breastfeeding may be offered if three hours have passed especially in LBW baby. If baby is fed by cup or nasogastric tube then measured amount of expressed breast milk may be given while baby remains in contact with maternal skin.

By accepting what mother says, thinks or feels about KMC, empathizing and praising her for doing good job boosts her confidence. It is very important that mother feels comfortable and some help is available to her for her own needs like toilet, eating and sleeping. Reading material and availability of television will keep her busy and less tense.

It is important to have a breastfeeding expert in place who can counsel her and train her for making good positioning and expression of the breast milk. Family support is extremely important. Other family members like grand mother and father can also be surrogate for the mother. However, advantage of KMC by mother outweighs anybody else.

KMC PROCEDURE

- Kangaroo positioning—Skin to skin contact between the mother and her upright baby between mother's breast on her bare chest and under her clothes.
- Head turned to one side in slightly extended position which allows open airways and eye to eye contact between baby and mother.
- Hips should be flexed and abducted in a "frog" like position and arms should be flexed.
- Baby's abdomen should be at the level of mother's epigastrium.

- Support the bottom of the baby with a binder. Binder's top should be just under the baby's ear.

MONITORING

- They should be careful about the position of baby's neck, which should not be too flexed or too extended.
- Baby's breathing
- Baby's skin color
- Baby's temperature (she should feel for baby's hand and feet)
- Number and consistency of stools
- Baby's weight (daily in hospital, otherwise weekly)
- Head circumference (should be checked once weekly)
- Reassure her that there is no danger if the baby has hiccups, sneezes
- Teach the mother (and family members) to recognized danger signs.
 - Breathing to fast or very slow
 - Chest indrawing, grunting
 - Frequent and long apnea
 - Body temperature low/high
 - Difficulty in feeding
 - Convulsions
 - Diarrhea
 - Yellow skin.

LENGTH OF KMC

Kangaroo mother care (KMC) may begin with 30 to 60 minutes. It is more to give support to the mother and making her confident. The duration may be extended to 6 to 8 hours in a stretch. It is desirable to do KMC for 24 hours with interruptions for changing diapers, hygiene, cord care of baby and for her own needs like changing sanitary pads or using toilet if not comfortable with KMC. Sessions shorter than 1 to 2 hours

should be avoided as frequent handling is stressful for the baby.

Daily bathing is not needed and it is not recommended. Bathing should be short with warm water (37°C). Baby should be dried thoroughly immediately afterwards wrapped in warm clothes and put back in KMC position quickly.

CRITERIA FOR DISCHARGE

- Good general health of baby and no concurrent infection.
- Feeding well and is exclusively or predominantly breast fed.
- Gaining weight (at least 15 gm/kg/day) for three consecutive days.
- Temperature is stable in KMC position for three consecutive days.
- Mother is confident in caring for the baby and is able to come for follow-up regularly.
- When baby starts showing signs of intolerance to KMC in the form of wriggling movement, becomes uncomfortable, cries and fusses every time mother tries to put her in pouch (usually at around 40 weeks of post-menstrual age).

Neonatal Myopathies

Veda V Vedanarayanan

Abstract

Weakness and hypotonia are the cardinal clinical presentation of myopathies in newborn. Arthrogryposis occurs in some of them with weakness and hypotonia. Myopathies result from a variety of causes in neonates and they include myotonic muscular dystrophy, congenital muscular dystrophy, congenital myopathy and metabolic myopathies. Clinical evaluation, electrodiagnostic tests, serum CK and metabolic tests are useful in evaluating these patients. Definitive diagnosis is made with muscle biopsy and genetic studies for mutations.

Muscle diseases are important causes of hypotonia and weakness in neonates. They present either as a floppy neonate or with arthrogryposis. The clinical syndrome of floppy neonate is very easy to recognize. It is characterized by reduced resistance to passive movements of limbs, limbs kept in positions that are unusual and laxity of joints. The causes for floppy neonates are several and include diseases of the brain, spinal cord and the motor unit. (Table 1). It is not uncommon to have a disease involve multiple sites involved in motor function. Clinical examination, imaging of the brain and spinal cord, comprehensive electrodiagnostic studies and muscle biopsies may be required to determine the cause of this syndrome. Arthrogryposis is a clinical syndrome that results from muscle weakness and/or reduced movement of joints in the intrauterine period. It is characterized by stiffness in joints secondary to contracture of soft tissues around the joints. It often involves the distal joints in upper and lower limbs. This often occurs with hypotonia and weakness and hence the syndrome of floppy infant and arthrogryposis may occur together.

The clinical evaluation at the bedside can often lead to localization of the cause for hypotonia and weakness. Diffuse encephalopathies from hypoxic ischemic injury, sepsis, metabolic disorders and from sedating medications often produces impairment of consciousness in the infant. Lack of alertness, spontaneous eye opening, weak and poorly sustained cry to stimulation are clues. Often the appearance of the infant provides more information about the state of alertness in the newborn period. It can be difficult to evaluate mental status in moderate to severe premature neonate. Babies with myelopathies are often alert, although weak and hypotonic in limbs unless the clinical picture is complicated by encephalopathy (often ischemic encephalopathy). In diseases of the motor unit (motor neurons, peripheral nerves, neuromuscular junction and muscle) neonates are often alert. The reduction in muscle tone is often more prominent in muscles of limbs and axial musculature, in contrast axial muscles are weaker than the limb muscles in encephalopathy. Tendon reflexes are absent or normal and may be hyperactive in encephalopathy. Arthrogryposis can occur in upper and lower motor neuron disorders.

LABORATORY EVALUATION OF HYPOTONIC NEONATES

The laboratory evaluation begins with measurement of serum CK. It is normal in encephalopathies and in disorders of motor neuron, neuromuscular junction and polyneuropathies. Even in neonates with myopathy serum CK is often normal. The serum CK is elevated in myopathies with muscle necrosis or leaky muscle membranes, such as in congenital muscular dystrophies, acid maltase deficiency and inflammatory myopathies. The currently used normal values for serum CK are from normal adults and normal values in normal healthy neonate are not available.

Table 1: Differences between central hypotonia and hypotonia from neuromuscular weakness

Item	Central hypotonia	Neuromuscular weakness
Alertness	Reduced often	Often normal
Muscle tone	Axial muscles > appendicular	appendicular > axial
Tendon reflexes	May be hyperactive	normal or absent
Neonatal reflexes	Persistence	loss of reflexes as in normal infants

The nerve conduction studies (NCS) and needle electromyographic (EMG) examination differentiates between disorders of muscle, nerve, neuromuscular junction and motor neuron. The performance of these studies in neonates, especially in those with arthrogryposis, is technically difficult. In neonates with myopathy the sensory nerve conduction studies are normal and the motor nerve conduction studies may show reduction in motor compound muscle action potential (CMAP) with normal conduction velocity, distal and F wave latency. Repetitive nerve stimulation studies (RNS) are normal. The needle EMG examination is the most critical part of the electrodiagnostic study. The spontaneous activity may show fibrillation potentials when muscle fiber necrosis is present, as in congenital muscular dystrophies. It is normal in most congenital myopathies where the muscle fiber necrosis is absent. The voluntary motor unit potentials are abnormal and have increase in polyphasic turns with reduction in amplitude and duration. The recruitment is often abnormal and shows a pattern of early recruitment (more than usual number of motor units are activated to achieve a given amount of force). The assessment of motor unit morphology and recruitment pattern can be difficult in neonates. Definitely abnormal EMG showing myopathic change makes the diagnosis of myopathy more definite; however a normal EMG cannot exclude a myopathy in neonates.

The gold standard for diagnosis of myopathies is comprehensive pathological examination of muscle biopsy. The examination includes a battery of histochemical stains: NADH reaction, SDH reaction, PAS stain, modified trichrome stain, cytochrome oxidase stains and oil red-O reaction. Immunocytochemical reaction for cytoskeletal proteins are integral part of evaluation.

Additional studies and clinical features can provide clues to diagnosis. Congestive cardiomyopathy with myopathy suggests Pompe's disease. Thin ribs, osteopenia of bones and bell shaped chests are seen in congenital myopathies and spinal muscular atrophy. Malformations of brain and eyes can be seen in patients with some forms of congenital muscular dystrophies. Electroencephalograph (EEG) may be required to determine if there is significant encephalopathy in babies.

The examination of parents, especially mother, can lead to diagnosis in the neonate. Congenital myotonic dystrophy in the newborn can be diagnosed with confidence in a floppy infant when the typical phenotype of myotonic dystrophy is seen in mother (weakness of face and distal muscles in limbs with myotonia). Roughly 1 to 10 percent of mothers with myasthenia gravis give birth to babies with transient neonatal myasthenia gravis. Babies born to mothers with congenital myopathies may have a more severe form neonatal onset. Myotubular myopathy, especially the X-linked variety is mild in severity in mothers. Congenital myopathies and congenital muscular

dystrophies are inherited by autosomal and sex linked inheritance, and hence it is not uncommon to find evidence of myopathy in parents or siblings.

CONGENITAL MYOTONIC MUSCULAR DYSTROPHY

This condition refers to the severe clinical neonatal presentation seen in some of the babies born to mothers with relatively mild myotonic dystrophy. This is one of the common causes for muscle diseases in neonates. The diagnosis is easily made by careful clinical examination of their mothers for muscle weakness and myotonia.

The pregnancy is often complicated by hydramnios and premature labor. The babies have severe hypotonia and generalized weakness with inability to suck and swallow and sometimes to breathe. The striking feature is bilateral facial weakness with a peculiar tented appearance to the lips. Contractures of distal joints are seen often. Cardiac arrhythmias are rare, and evidence of smooth muscle dysfunction present as abdominal distention and dysmotility of the gastrointestinal tract. Unlike in adults with myotonic dystrophy, myotonia is absent on clinical and needle EMG exam.

The disorder is from intronic expansion of CTG repeats in myotonin gene located on chromosome 19. The size of the expansion is greater than 1000 repeats in neonates with CMD unlike in the affected adults where the repeat numbers are in 100s. The diagnosis can be confirmed by DNA studies showing the CTG repeat expansion in myotonin gene.

Muscle biopsy is not required for diagnosis, with the availability of genetic studies. The muscle biopsies done in the past have shown type 1 muscle fiber atrophy, increase in fibers with internalized nuclei. These biopsies are indistinguishable from patients with centronuclear myopathy (discussed below).

Management is supportive in the neonatal period. Most infants will improve over time. Breathing and feeding improve over weeks and majority of patients will walk by 2 to 3 years of age. Mental retardation is common and variable.

CONGENITAL MUSCULAR DYSTROPHY (CMD)

This term refers to a group of disorders characterized by weakness, hypotonia and frequently with joint contractures in neonates and dystrophic muscle biopsy (muscle fiber necrosis, regeneration and scarring). The weakness and hypotonia are seen in axial and appendicular muscles and contractures are often seen in distal joints and rarely proximally. Abnormalities of the brain and eye occur with some forms of congenital muscular dystrophies. Based on recent knowledge of the biochemical defect, CMD are classified into four groups:

Group 1: Defects in the laminin alpha-2 (Merosin) in the basement membrane;

Group 2: Abnormal glycosylation of alpha-dystroglycan;

Group 3: Disorder of collagen VI

Group 4: Reduction in integrin alpha 7, laminin alpha 2 receptor with normal levels of laminin alpha-2

CMD FROM DEFICIENCY OF LAMININ ALPHA-2

Reduced fetal movements are frequent and neonates are often severely weak. Difficulty with breathing, suck and swallow are common. Joint contractures, often distal in distribution, are common. Partial external ophthalmoplegia is seen in some of the patients. The serum CK is elevated, usually 10 to 150 times of normal and it decreases with reduction in muscle bulk over years. Seizures are seen in 8 to 30 percent of patients. The intelligence in later life is normal. Magnetic resonance imaging (MRI) of the brain is abnormal and shows bright T2 lesions in periventricular white matter, however the white matter in the cerebellum and brain stem are normal. Heterotopias in cerebral hemispheres, focal cortical dysplasia and irregular cortical laminations occur in some.

Muscle biopsy shows patchy areas of muscle fiber necrosis and regeneration with endomysial fibrosis. Immunohistochemical staining for laminin alpha-2 (merosin) is absent and confirms the diagnosis.

CMD FROM DISORDERS OF GLYCOSYLATION

Four forms of CMD occur from disorders of glycosylation of alpha-dystroglycan. Dystroglycan is the central component of the dystrophin-glycoprotein complex. It is critical for the normal maturation in brain, eye and muscle. All four forms of CMD present with severe, generalized hypotonia and weakness. Brain and eye involvement is seen in all forms and they vary in severity. In Walker Warburg syndrome (the most severe form) the brain shows type 2 lissencephaly. In other forms varying degrees of disturbance in neuronal migration occurs such as: pachygyria, heterotopia or cortical dysplasias with hydrocephaly. The eye involvement ranges from total loss of vision to high myopia. The different types of CMD from glycosylation defect are:

Disorder	Gene
Fukuyama CMD	Fukutin
Muscle eye brain disease	POMTGnT1
Walker Warburg syndrome	POMT1
CMD 1C	FKRP
CMD 1D	LARGE

The strength and function improves over time. The prognosis is often complicated by the presence of brain and eye abnormalities.

CMD FROM COLLAGEN 6 DEFECTS (ULLRICH'S CMD)

Collagen 6 disorders present a phenotypic spectrum, ranging from severe phenotype in the neonatal period to a milder phenotype presenting in adulthood. The neonatal phenotype presents with hypotonia and weakness at birth. Contractures are seen in proximal joints, often with kyphoscoliosis and torticollis. Joint laxity is seen distally. The calcaneus is prominent and protruded. No central nervous system involvement is seen and intelligence is normal. The serum CK is normal or slightly elevated. The muscle biopsy shows dystrophic features as in other CMD. The diagnosis is made by DNA studies on collagen 6 gene.

CONGENITAL MYOPATHIES

This group of muscle disorders is defined by specific histopathological changes, lack of progression or improvement in most instances. Some of the congenital myopathies present in neonatal period and others are detected in infancy, childhood and sometimes later. In patients becoming symptomatic in neonatal period, generalized weakness and hypotonia are the prominent clinical signs. Difficulties with suck and swallow are common and respiratory failure can be seen sometimes. Facial abnormalities can be seen and consist of long myopathic facies with tented lips. High arched palate is present in all. The weakness is generalized in distribution involving trunk, limb, facial and bulbar muscles. Extraocular muscles are involved in some of the congenital myopathies, and present as limitation in eye movements and ptosis. The ribs are often thin on X-rays and pectus excavatum, bell shaped chest are seen due to weakness of the chest wall muscles and diaphragm. Serum CK is usually normal. The EMG is myopathic or normal without fibrillations. Involvement of heart, brain, eyes or other organ system is generally absent unless they are secondarily involved due to the muscle weakness.

Nemaline Myopathy

This condition is characterized by rod or thread-like structures in cytoplasm of muscle fibers. In addition there is atrophy of type 1 fibers (Fig. 1). The severe congenital form presents in neonatal period with profound muscle weakness. Arthrogryposis is rare and cardiomyopathy is seen rarely. Early mortality is common although some may survive long-term. The gene defects are heterogeneous and in the autosomal recessive form, mutations have been described in the genes coding for nebulin and tropomyosin.

X-Linked Myotubular Myopathy

This myopathy is characterized by the presence of central nuclei in numerous muscle fibers and is similar in appearance to the myotubes. Type 1 fibers are small (Fig. 2). The

Fig. 1: Muscle biopsy stained with modified trichrome stain showing nemaline rods (*For color version see plate 22*)

Fig. 2: Myotubular myopathy. H&E stain, showing many muscle fibers with central nucleus (*For color version see plate 22*)

X-linked recessive form presents in neonatal period with profound weakness and frequently with respiratory failure. The babies are usually long, often greater than the 90 percent in length, and have macrocephaly with hydrocephalus in some. Feet and fingers are often long and face is long. Ptosis with limitation of extraocular movements is seen in many. Ambiguous genitalia occurs rarely in these infants. The mortality is high, although there are reports of improved survival in some of these babies.

The mutation is in the myotubularin gene, a highly conserved gene responsible for regulation of genes involved in normal growth and maturation of muscle fibers. The exact mechanism involved in the pathogenesis is not clearly understood.

Congenital Fiber Type Disproportion

This congenital myopathy is characterized by selective atrophy of type 1 fibers with a predominance of type 1 fibers. This disorder begins in infancy and often improves over time. Contractures, scoliosis and hip dislocation are common. The strength and function improve over time. The genetic defect is unknown.

METABOLIC MYOPATHIES

Infantile Acid Maltase Deficiency

This disorder results from a deficiency of acid maltase, a lysosomal enzyme. The myocardium, neurons and other several organs are involved besides the muscle. The

myopathic symptoms are prominent and the affected babies present with hypotonia and weakness and often heart failure from cardiomyopathy. Cardiomegaly on chest X-ray is often striking with evidence of left ventricular hypertrophy on EKG. The serum CK is high. Myopathic motor units and fibrillations are seen on needle EMG. Muscle fiber necrosis with regeneration and vacuolar change in cytoplasm of muscle fibers are prominent on muscle biopsies. The vacuoles contain PAS positive material and stain positively with acid phosphatase. The activity of acid maltase is severely reduced in muscle and similar reduction can be shown in leukocytes. DNA mutation studies can be performed on peripheral blood.

Treatment is supportive and mortality is high. Treatment trials with enzyme replacement are being evaluated.

Other Metabolic Myopathies

Disorders of fatty acids, medium and long chain fatty acid present in neonatal period with muscle weakness, encephalopathy and elevated serum CK. The neonatal form of carnityl palmityl transferase 2 present with hypotonia and elevated serum CK and episodes of myoglobinuria can be brought on by periods of fasting.

Myopathy and encephalopathy are clinical presentations of mitochondrial disorders in the neonatal period. They can result from deficiency of complex 1, 3, 4. These patients have lactic acidosis from birth. Some of these phenotypes are fatal. One phenotype of complex 4 deficiency causes severe muscle weakness in the neonatal period and then spontaneously reverses by age 1.

OTHER MYOPATHIES

Primary inflammatory myopathies are rare in neonates. There are few reports of neonatal idiopathic polymyositis. The diagnosis in these patients has been made on routine histochemical stains and have not had full battery of immunocytochemical staining for cytoskeletal proteins, hence it is not certain if they have primary autoimmune inflammation or if the inflammatory reaction is a secondary process.

Advances on Rotavirus Disease

Puneet Kalra, Gajanan Namjoshi, Anupam Sachdeva

Rotaviruses are the most common cause of severe diarrheal disease in infants and young children worldwide.

Rotavirus is a nonenveloped Ribonucleic acid (RNA) virus discovered in 1973 by Ruth Bishop and colleagues, at the Royal Children's Hospital in Melbourne, Australia. In 2004, rotavirus infections were estimated to cause approximately 527,000 (475,000—580,000) deaths, predominantly in developing countries. Although the viral strains show considerable diversity, 5 serotypes are responsible for the majority of human rotavirus disease. Rotaviruses cause gastroenteritis especially among children of less than 5 years age worldwide and acute diarrhea in the young ones of many other mammalian species (calves, piglets, lambs, rabbits, etc.) and of birds.

ROTAVIRUS STRUCTURE, STRAINS AND SERODIVERSITY¹⁻⁸

The structure of rotavirus is complex. It is called as rotavirus due to its wheel-like structure when observed under electron microscope. (Rota = wheel in latin).

Rotavirus genome has 11 segments of double stranded RNA. This genome codes for six structural proteins (VP1-VP4, VP6, VP7) and six nonstructural proteins (NSP1-NSP6).

Following are the layers that surround the genome (Fig. 1):

Core: Inner layer that surrounds the genome and has viroproteins VP1, VP2, VP3.

Inner capsid: Intermediate layer made-up of VP6.

Outer capsid: Outer layer that has VP7 at surface and VP4 as projections.

The viral antigens like VP4 (also called P because it is lysed by intestinal protease during viral entry), VP7 (Also called G because it is a glycoprotein), VP6 (that forms inner capsid) and NSP4 (which acts as enterotoxin) are

Fig. 1: Schematic presentation of rotavirus vaccine

important in the pathogenesis of disease and also in the protection against rotavirus infection. VP4 and VP7 elicit neutralizing antibodies and therefore considered to be involved in immune protection. Also these antigens are of importance in understanding classification and nomenclature of rotaviruses.

CLASSIFICATION OF ROTAVIRUSES

Based on inner capsid protein (VP6) there are seven groups of rotaviruses (A to G) Group A, B and C all of which cause human infection, the most common being group A. Within group A, rotaviruses are classified using a binary system (similar to influenza). For this the serotyping and genotyping methods are used.

G types: For G types, antigen serotype and genotype matches and therefore these types are mentioned based on serotype alone as G1, G2, G3, etc.

P types: For P types, there is greater number of genotypes than serotypes and concordance between serotype and genotype is rare. Hence P type is denoted as serotype, followed by the genotype (mentioned in brackets), e.g. P1(4), P1(8).

Nomenclature of Rotavirus

Binary nomenclature of rotavirus strain is used based on G and P type of that virus, for example, G1P1(8), G2P1(4). In short it can be mentioned only using genotype of P, e.g. G1P(8) G2P(4).

Serodiversity of Rotavirus Strains

The segmented nature of rotavirus genome allows for gene reassortment when a single cell is coinfecting by two different rotavirus strains. Theoretically this property has potential to generate two raised to power 11 different combinations of G and P proteins. In practice the number of G and P combinations is less.

Peculiarity of rotavirus is that the predominant strains show diversity with regards to region.

Globally Common Strains of Rotavirus

Four common G types (G1, G2, G3 and G4) in conjunction with P[8] or P[4] form over 88 percent of the strains analyzed worldwide. In addition, serotype G9 viruses associated with P[8] or P[6] were shown to have emerged as the fourth globally important G type with the relative frequency of 4.1 percent.

Common Strains in India

The Indian Rotavirus Strain Surveillance Network was established with four laboratories and 10 hospitals in seven different regions of India.

In this network, the stool samples of hospitalized cases for age in children <5 years were tested. From December 2005 through November 2007, Rotavirus was markedly seasonal in northern temperate locations but was less seasonal in southern locations with a tropical climate.

The most common types of strains were G2P[4] (25.7 percent of strains), G1P[8] (22.1 percent), and G9P[8] (8.5 percent); G12 strains were seen in combination with types P[4], P[6], and P[8] and together comprised 6.5 percent of strains. This study showed the regional diversity in rotavirus strains.

As opposed to global scenario wherein G1P8 strain was most common; this landmark study established that in India the scenario was a little different with G2P4 being the most common strain.

There are studies across world which found different emerging strains of rotavirus like G9, G10, G12. Out of emerging strains, only G9 has gained epidemiological importance.

Rotavirus Burden and Epidemiology^{4,9-13}

Rotavirus is the most common cause of severe gastroenteritis in infants and young children less than 5 years worldwide.

Clinical spectrum of rotavirus gastroenteritis (RVGE) ranges from mild to severe watery diarrhea with abrupt onset of fever and vomiting. (Vomiting precedes diarrhea in most cases).

It can result in dehydration, electrolyte disturbances, shock and even death.

Most common age group for severe gastroenteritis is in children aged 6 to 24 months.

The disease is of universal occurrence across developed and developing world.

Clean water supplies and good hygiene have not had a substantial effect on control of RVGE.

Global Rotavirus Burden

Rotavirus accounts for annual 6,10,000 deaths, 2.4 million hospitalizations, 24 million clinic visits and 114 million of rotavirus disease episodes.

Rotavirus epidemiology in developing world is characterized by a high mortality (about 85% of global mortality occurring in developing countries), serodiversity of strains, occurrence of coinfection by other enteric pathogens and earlier age of severe disease.

Rotavirus Burden in India

Burden of disease: Rotavirus diarrhea is one of the largest causes of child mortality in India. Amongst total rotavirus mortality in world, India accounts for the highest number of deaths due to RVGE. As per recent surveillance, rotavirus is associated with 39.2 percent of all diarrhea-related hospital admissions among children aged <5 years in India.

Every year in India, rotavirus diarrhea causes an estimated 122,000 to 153,000 deaths, 457,000 to 884,000 hospitalizations and 2 million outpatient visits in children <5 years of age.

As per recently published estimates for rotavirus global mortality, in 2008, diarrhea attributable to rotavirus infection resulted in 453,000 deaths (95% CI 420,000–494,000) in children younger than 5 years—37 percent of deaths attributable to diarrhea and 5 percent of all deaths in children younger than 5 years.

Five countries accounted for more than half of all deaths attributable to rotavirus infection: Democratic Republic of the Congo, Ethiopia, India, Nigeria, and Pakistan, India alone accounted for 22 percent of deaths (98,621 deaths).

Protection Against Rotavirus After Natural Infection¹⁴⁻¹⁶

Immune mechanisms that are responsible in rotavirus disease occurrence or protection from it are complex and not completely understood. Also there is no defined correlate of protection for rotavirus disease. There are multiple studies which involved follow-up of birth cohort to evaluate if the previous infection with rotavirus (symptomatic or asymptomatic) offered protection against subsequent infection or disease. A study by Velazquez et al which had birth cohort of 200 new births that was followed up for 2 years, found that natural infection offers protection from subsequent disease. The protection is complete against the moderate to severe disease if there are two previous infections. This study formed the basis for developing rotavirus vaccines and its dosage.

In a recent landmark study by Gladstone et al which was conducted in Vellore, the birth cohort of about 400 newborns was followed up for 3 years. It was found that the protection offered by the natural rotavirus infection against moderate to severe diarrhea is only 79 percent after 3 previous rotavirus infections. Reinfections were common and subsequent infections were not always mild or less in severity. Based on these results, authors of the study were of the opinion that more number of doses or increasing the dose or early (neonatal or maternal) vaccination may be options to get better efficacy of rotavirus vaccines in Indian setting where efficacy of the vaccine (and in general other oral vaccines) is found to be less as compared to developed world.

Available Rotavirus Vaccines: Efficacy, Effectiveness and Safety¹⁷⁻²⁶

The much publicized previous attempt at a vaccine, Rotashield was licensed in the United States in 1998. It had been shown to be efficacious in reducing the frequency of severely dehydrating rotavirus. Furthermore, it was cost effective and the strategy was clear; to use the high-priced vaccine routinely in industrialized countries to subsidize its use in developing countries. However, postmarketing surveillance detected an apparent increase in a relatively rare event, intussusception. The relationship was most strong when the first dose of vaccine was given with the first or second dose of the diphtheria—pertussis—tetanus vaccine. In the ensuing controversy, there was a reversal of the recommendation for universal immunization in the United States, leading to a withdrawal of the vaccine from the market, precluding the possibility of its deployment in developing countries.

Undeterred by the failure of Rotashield, pharmaceutical companies have persisted in developing alternatives. There were two vaccines that were developed later: RotaTeq which is a human bovine pentavalent vaccine and it is recommended to be used in three dose schedule that fits into the ongoing primary vaccination schedule. RotaTeq is ready to use fully liquid vaccine, available in latex free dosing tube.

Another vaccine, Rotarix is monovalent attenuated human rotavirus vaccine and it is recommended to be used in two doses. In India, the available formulation of Rotarix needs reconstitution. In China, there is a lamb derived rotavirus vaccine which is not licensed outside China and not much data is available about this vaccine.

The two vaccines: RotaTeq and Rotarix underwent robust clinical trials before approval for use. Each of these two trials recruited and followed more than 60,000 infants, making them the largest prelicensure vaccine trials conducted to evaluate vaccine safety (intussusception in particular). Importantly, neither of the trials have noted a significant difference in cases of intussusception (or other serious adverse events) between vaccine and placebo based on which the global bodies have declared the vaccines to be safe.

RotaTeq phase III clinical trial was conducted in 11 countries across three continents and it showed efficacy of 98 percent against severe RVGE and 74 percent against any severity of RVGE. It also demonstrated efficacy against different rotaviruses prevalent in the region.

Rotarix phase III clinical trial was conducted in 11 Latin American countries and Finland. The efficacy of the vaccine against severe rotavirus gastroenteritis and against rotavirus-associated hospitalization was 85 percent and reached 100 percent against more severe rotavirus gastroenteritis.

The results from both vaccines cannot be compared to determine which vaccine is superior as the studies were conducted in different settings and countries and also the scales used for scoring severity of gastroenteritis were different. Till date there is no head to head comparison study of RotaTeq and Rotarix.

The development rationale of these two vaccines differed. Both the vaccines try to simulate protection after natural rotavirus infection. RotaTeq followed the modified Jennerian concept and developed human-bovine reassortant vaccine. Bovine strain is naturally attenuated for human infection and pathogenesis and with the bovine genetic background, the vaccine has human antigens as G1, 2, 3, 4 and P(8) so that the vaccine would be safe and also immunogenic and efficacious. It included the most common rotavirus antigens that are prevalent globally. The three doses schedule was used based upon the earlier studies that showed good immunogenicity of three doses and finding from Velazquez study that at least two natural infections are essential to offer protection against severe disease and three infections to offer protection against mild disease.

Rotarix is an attenuated human rotavirus vaccine. It contains a single attenuated human rotavirus strain G1P(8). It was developed as two dose vaccine based on results of study on protection after natural rotavirus infection (Velazquez et al) that showed complete protection against severe disease after two natural infections.

Both the vaccines also demonstrated good efficacy in reducing health care resource utilization (HCRU) for

rotavirus gastroenteritis. In post-licensure period also, the vaccine has proven to be highly effective in developed world and the seasonal epidemic peaks of rotavirus disease in US are now almost absent.

Safety of vaccines was also established in post-licensure surveillance studies. In Australia, there was a small increased risk of intussusception found for both the vaccines. In Mexico and Brazil, monovalent vaccine was found to be associated with small increased risk of intussusception after vaccine administration, that led to label change of monovalent vaccine by US FDA.

For pentavalent rotavirus vaccine, such increased risk was not found in US.

However, it is noteworthy that this small increased risk in some settings is definitely not a cause of concern as the vaccines are highly effective and benefits outweigh the risk.

In developing countries also, these vaccines were evaluated and though the efficacy of both vaccines was less as compared to developed world, the impact can be substantial looking at the burden of disease in these countries. WHO also has endorsed the use of rotavirus vaccines in national immunization schedule at global level after reviewing this data of developing countries clinical trials of RotaTeq and Rotarix. Rotarix was evaluated in South Africa and Malawi while RotaTeq was evaluated in Africa (Ghana, Kenya, Mali) and also in Asia (Vietnam and Bangladesh). Efficacy for protection against severe RVGE ranged between 51 to 64 percent in these trials.

Vaccines in Pipeline for Rotavirus¹⁷

Research is continuing in the field of rotavirus vaccine. Presently some vaccines are in the clinical trial. These include: A human neonatal P[6]G3 strain, RV3, developed by Bishop and colleagues in Australia, a human bovine reassortant vaccine developed by Albert Kapikian and presently undergoing development and trials at different countries and a neonatal strain vaccine (G9P11) being developed by Bharat Biotech in India. This G9P(11) virus strain has the VP4 of bovine rotavirus origin, and all other segments of human rotavirus origin. Other approaches to the development of rotavirus vaccines are also being pursued. Rotavirus antigens for parenteral delivery have received some attention as virus-like particles prepared in baculovirus, expressed antigens, DNA vaccines, and killed virus. These novel approaches are being pursued using animal models.

SUMMARY

There is definite role the rotavirus vaccines have played in developed world. Now, it is the turn of developing countries like India where rotavirus disease burden is the highest to get the benefits of the rotavirus vaccines.
